Foreword

Critical Care Toxicology belongs in every critical care unit, emergency department, poison center, library, emergency response center, and on the most easily reached shelf for anyone interested in or who comes in contact with medical toxicology. This masterful compilation of information has many attributes, among which are:

- Evidence based well-referenced information
- Editors and authors who are experts in their fields
- Concise and clear presentation
- Tables that convey critical data
- Figures and diagrams that are clinically relevant
- Paragraph headers that allow focused access to information
- Calculations and formulas that are fully explained
- Lists of treatment materials to obtain in advance with contact information of unusual items
- Therapeutic dosages that are detailed enough to be utilized without additional references

In most cases, diagnostic and therapeutic information can be obtained in a few minutes given the book's careful organization. For those patients presenting with complicated or multiple exposures, the structure provides a straightforward method of rapidly developing and working through a differential diagnosis.

The quality of this book should come as no surprise after looking at the impressive listing of authors. The editors, each of whom I have known, worked with, and respected for many years, have selected an international group of experts whose credibility is unmatched. They represent the best of our profession of medical toxicology and have written a large percentage of the most important and groundbreaking publications in our field. The editors and authors are the most sought-after educators in our annual toxicology meetings around the world and provide clinical expertise as well as leadership and training for all of us who work in this wide and varied area.

In the preface to the first edition of *Critical Care Toxicology*, the word "passion" occurs in the very first sentence. For all of us who have ever written a scientific monograph, paper, chapter, book, or prepared a teaching session, the word passion certainly defines a major requirement for preparation of materials

that will communicate the knowledge that is intended. It takes time and effort to write something that will stand the test of time, and when written with passion it means that the author has not skipped over anything and left nothing of importance unaddressed. It requires thorough knowledge of the subject, real world experience, fully researched literature, and draft after draft until communication is assured. When reading this book, it is apparent that the editors and authors have achieved their goal.

Before writing this foreword, the editors provided me with some chapters from the second edition. In reviewing four of them – “Acid-base,” “Hypotension and Shock,” “Seizures,” and “Acute Respiratory Distress Syndrome” – it was readily apparent that this second edition is an improvement on an already excellent book. More current materials are included as expected, but using these chapters as examples the authors have dramatically improved this book. Acid-base in the critical care setting is a complicated and often difficult issue. To address that the authors have doubled the length of this chapter and substantially added information which will be valuable to all who utilize it. The chapters on hypotension and shock and acute respiratory distress syndrome have been broken out of their previous locations and addressed comprehensively to reflect their importance. The chapter on seizures has also been doubled in length and contains a considerable amount of new information that is clearly presented.

The authors have also added speed of access to this book through the use of a table of contents at the beginning of each chapter. This further enhances the ability of the reader to get to an answer under emergent circumstances.

The book also has another purpose than just providing critical information in a clinical setting. It provides a very readable and understandable educational experience for all those who are studying this area. This must include addressing controversial areas with which the reader may be familiar and if not familiar ought to be familiar, and this book engages all of this.

Even those of us who have been in this field for a long time stand to learn something from this book. The discussion of the strong anion gap in the acid-base chapter coupled with the very practical explanations of the other factors in this important area is the clearest I have ever read. An area in which I have little knowledge is malignant hyperthermia, and this chapter provides a clear explanation along with even a phone number and website to get additional updated information in what is apparently a rapidly evolving issue. The editors clearly want readers to get the right answers to their questions.

Critical Care Toxicology covers all of the areas in medical toxicology in a series of well-written chapters following the excellent chapters that provide an approach to the critically poisoned patient and an understanding of toxic syndromes. Images of various aspects of toxicological encounters provide visual reinforcement of the written materials.

The index is very well done and comprehensive. Unlike the 7th edition in 1959 of Nelson’s pediatric text where the editor’s daughter, who hated having to produce the index, entered under B “Birds, for the” and listed the entire book, the index of *Critical Care Toxicology* was obviously prepared by someone who had a passion for helping readers get to answers.

Critical Care Toxicology provides a very valuable contribution to all aspects of medical toxicology from education to, as the title states, critical care. It should be readily accessible to everyone who may face this issue from forming a differential diagnosis to rendering care.

Preface to the Second Edition

Those readers who are familiar with the first edition of *Critical Care Toxicology* (CCT) know that it was about passion – our collective passion for caring for patients with the group of fascinating physiological derangements caused by exogenous chemical exposures. While our passion for the field of clinical toxicology remains unabated, an additional theme that characterizes the second edition of *Critical Care Toxicology* is scientific evidence.

In the 10 years since the publication of the first edition, a considerable body of new scientific evidence has emerged, new antidotes have become available, and systematic reviews and meta-analyses have become more commonplace in the field of clinical toxicology. Seizing upon the opportunity to provide a compendium of this accumulated evidence-based knowledge, we have worked with our chapter authors to assure that they have stayed true to the existing body of empirical data and, in the many places, where data gaps exist identify them so that the user of this book will understand the basis for the treatment recommendations we provide. In order for the user of CCT to quickly discern the veracity of the evidence supporting the treatment recommendations provided, we have adopted the US Public Health Service's rating of scientific evidence. These gradings allow the reader to instantly know the level of scientific support for various treatment recommendations and thus to be able to rely most heavily on well-supported therapeutic modalities.

We are highly cognizant of the reality that there are many areas where the evidence base relating to treatment decisions is insufficient. Nevertheless, the clinician treating the critically poisoned patient still requires guidance. Given that so many of our chapter authors represent the world's authority on their topic, we have also strongly encouraged them to give their highly informed opinions on how to proceed in the many areas where there are clear knowledge gaps. Where they have supplied these opinions they have been identified as such, and we have worked with them to also explain their thought processes underlying these opinions.

We are very proud of the group of chapter authors that have been brought together in CCT. Where possible we have endeavored to recruit a group of international experts in their respective subject matter who are also experienced clinicians, proficient in the intensive care of patients poisoned by the toxins and toxicants they have addressed. This quest for such a uniquely qualified group of chapter authors has required us to seek out scholars from many areas of the world. Being such highly respected individuals, our chapter

authors are for the most part very busy with their various academic and clinical pursuits. We are greatly indebted to them for the generous donation of the time they gave us to not only produce their excellent chapters but also to put up with our compulsively detailed editing and challenges to them for justification of the information contained in their chapters. In most instances, they have done so because they were dedicated to the idea of working with us to achieve the goals enumerated above.

Critical Care Toxicology is not a static textbook in the traditional sense. The online version is a living dynamic document that can, and will, be updated as needed and new chapters will be provided beyond the date of the original publication of the current edition. In this way, we will feel confident that you, the reader of CCT, will have the most up-to-date information available to you in your care of your critically poisoned patients.

Preface to the First Edition

To us, this book is about passion. It is the result of the passion we share for the clinical challenges we face every day in caring for critically poisoned patients and in understanding their unique and enchanting pathophysiology and its therapeutic implications. This is a passion we hope to elicit in all who venture into the world of clinical toxicology as they read this book. To the medical toxicologist, the care of the seriously poisoned patients merges the diverse worlds of critical care, emergency medicine, pharmacology, altered drug pharmacokinetics (hence the term “toxicokinetics”), diagnostic challenges, multisystem involvement in often otherwise healthy patients, and the use of specific and often esoteric treatment strategies and antidotes.

Before embarking on the extraordinarily labor-intensive activity of generating a book of this depth and complexity, we queried the importance of producing another clinical toxicology textbook. We are aware of several excellent general clinical toxicology textbooks on the market and appreciate their attempts to achieve a far greater breadth than the present work. However, toxicology is such a broad field that general textbooks encompassing all of clinical toxicology necessarily must limit the extent of their coverage of the intensive care unit management of major poisonings. Thus, the intensivist, and critically poisoned patients, deserve a reference that specifically addresses their needs. This need is made all the more important by the life-threatening nature of many of these poisonings. Stark evidence of the complexity of just these issues is that to cover them adequately required 160 chapters and 1633 pages.

Our goal was to have the most knowledgeable and experienced medical toxicologists author relevant chapters. In order to achieve this goal we drafted our colleagues with unique experience and expertise worldwide. As witnessed by our contributor list, all continents, except Antarctica, are represented. We proudly boast that our collective chapter authors represent a significant proportion of the most experienced critical care toxicologists in the world. Medical toxicologists interested in acute care tend to be domiciled at the bedside, in poison centers, or both. Because of the highly clinical nature of this book, we selected authors with a predominantly bedside care orientation.

With the ready access to facts and data via the Internet, the very nature of hard copy books has changed dramatically. No longer is it necessary for books to be compendia of facts. However, electronic databases cannot convey the reasoned clinical approaches and the synthesis of pathophysiology with

clinical effects and treatment that characterizes the pages that follow. Certainly, important physiologic and monitoring parameters as well as drug dosages are amply provided. The degree to which they are included represents our view of the best balance between those that are important to know and the desire to dedicate as much space as necessary to an elucidation of relevant concepts and a critical discussion of therapeutic controversies. We have embraced rather than glossed over controversies. The reader will find that this is not simply a “how to” handbook. Our aim is to provide the practitioner with the data needed to care for his or her individual patients. As an aid to those who choose to delve more deeply into the concepts, approaches, and controversies in this book, chapters are well referenced with primary source citations.

It is our hope and expectation that this book will evoke the same passion in the reader that the subject does for us.

About the Editors

Jeffrey Brent holds the rank of Distinguished Clinical Professor of Medicine, in the Division of Clinical Pharmacology and Toxicology, at the University of Colorado, School of Medicine. He holds secondary appointments in the Departments of Emergency Medicine and Pediatrics and in the Colorado School of Public Health.

Dr. Brent has received numerous awards and honors during his professional career. Among these are multiple career achievement awards, including the Louis Roche Award by the European Association of Poisons Centres and Clinical Toxicologists, the Career Achievement Award by the American Academy of Clinical Toxicology, the Ellenhorn Award by the American College of Medical Toxicology, and the Clinical Translational Toxicology Career Achievement Award by the Society of Toxicology.

A former President of the American Academy of Clinical Toxicology, Dr. Brent has also served on the board of directors of the American College of Medical Toxicology.

Dr. Brent has served as a consultant to the World Health Organization and to several US government agencies, including the Department of Health and Human Services, and the National Vaccine Program. Currently, he is an active consultant with the US Food and Drug Administration.

Dr. Brent is Director of a large National Institutes of Health and Food and Drug Administration supported multicenter research group in clinical toxicology known as the Toxicology Investigators Consortium.

Keith K. Burkhardt Dr. Burkhardt is the Senior Advisor for Medical Toxicology and Lead Medical Officer for the Biomedical Informatics Team in the Division of Applied Regulatory Science in the Office of Clinical Pharmacology within the Office of Translational Science in the Center for Drug Evaluation and Research at the FDA. He is board certified in Emergency Medicine and Medical Toxicology. He is a Clinical Professor of Emergency Medicine at the Penn State University. He practices critical care toxicology at the PinnacleHealth Hospital System. He is the former Medical Director of the Penn State Poison Center. Dr. Burkhardt received his medical toxicology training at the Rocky Mountain Poison Center in Denver. He received his emergency medicine training at the University of Cincinnati. He is a graduate of the former Medical College of Pennsylvania, now Drexel University. He is a past President of the American College of Medical Toxicology. His FDA work focuses upon using bioinformatics and cheminformatics tools to data mine the FDA Adverse Event Reporting System to learn mechanistic insights into drug safety issues.

Paul Dargan Professor Paul I Dargan is a Consultant Physician and Clinical Toxicologist and Clinical Director at Guy's and St Thomas' NHS Foundation Trust, London, UK. He is also a Professor of Clinical Toxicology at King's College London. He has an active research program with a focus on recreational drug toxicity, new psychoactive substances, prescription medicine misuse, self-poisoning (in particular, paracetamol/acetaminophen), and heavy

metal toxicity (in particular, lead). He has published over 250 peer-reviewed papers and numerous book chapters. He is active in postgraduate training in clinical toxicology and in undergraduate education of medical students at King's College London Medical School. He is a board member of the European Association of Poisons Control Centres and Clinical Toxicologists, and the Asia Pacific Association of Clinical Toxicology. He sits on the UK Advisory Council on the Misuse of Drugs (ACMD) and the Scientific Committee of the European Monitoring Centre for Drugs and Drug Addiction (EMCDDA). He is an expert adviser to a number of other bodies, including the US Food and Drug Administration (FDA) and the World Health Organization (WHO).

Benjamin Hatten Dr. Hatten received his M.D. in 2006 at the University of Texas – Southwestern Medical Center in Dallas, TX. After completion of this degree, he entered residency in emergency medicine at Denver Health Medical Center in Denver, CO. Subsequently, he entered the medical toxicology fellowship training at Oregon Health and Science University in Portland, OR. During his fellowship, he simultaneously obtained a Masters in Public Health in epidemiology and biostatistics. Upon completion of his fellowship and M.P.H. degree, he returned to Denver in 2013 and joined the faculty at the University of Colorado School of Medicine, the Rocky Mountain Poison and Drug Center, and Toxicology Associates. He is currently an Assistant Professor at the University of Colorado School of Medicine with a primary appointment in the Section of Medical Toxicology, Department of Emergency Medicine. In addition, he is an attending physician at the Rocky Mountain Poison and Drug Center as well as a member of Toxicology Associates, Prof. LLC – a hospital based, single specialty medical group dedicated solely to medical toxicology. Dr. Hatten is board certified in both emergency medicine and medical toxicology.

Bruno Mégarbane is Professor of Critical Care Medicine at Paris Diderot University and directs a research team at INSERM UMRS-1144. He is the Head of the Department of Medical and Toxicological Critical Care at Lariboisière Hospital, Assistance Publique – Hôpitaux de Paris, in Paris, France. He is the current President of the European Association of Poisons Centres and Clinical Toxicologists (EAPCCT). He conducted several clinical and experimental studies in clinical toxicology, mainly regarding mechanisms of opioid-related respiratory toxicity, prognostic factors of life-threatening poisonings, and management of refractory cardiotoxicant poisonings using ECMO. He is a member of the EXTRIP group and an Associate Editor for *Clinical Toxicology*.

Robert Palmer Clinical Assistant Professor, Medical Toxicology, Emergency Medicine, School of Medicine, University of Colorado, Aurora, CO, USA. Attending Toxicologist and Faculty, Medical Toxicology Fellowship Program, Rocky Mountain Poison and Drug Center, Denver Health and Hospitals Authority, Denver, CO, USA.

Dr. Robert Palmer received his undergraduate degree in chemistry from the University of Idaho. His M.S. and Ph.D. degrees were obtained in organic-medicinal chemistry from the University of Washington in Seattle. He completed a postdoctoral appointment at the University of Washington Health Sciences Center, followed by joining the faculty at the University of New Mexico in Albuquerque. Dr. Palmer then relocated to Colorado and completed a fellowship in clinical toxicology at the Rocky Mountain Poison and Drug Center (RMPDC) in Denver, CO. He is board certified in clinical toxicology

and an elected Fellow of the American Academy of Clinical Toxicology. Dr. Palmer maintains a faculty position at RMPDC teaching in the medical toxicology fellowship program, as well as serving as an attending toxicologist on the medical toxicology clinical service. He is a member of multiple medical and scientific associations and lectures locally, nationally, and internationally. He has authored over 50 scientific papers and more than 30 book chapters. Among his clinical and research interests are postmortem toxicology and opioid abuse.

Julian White is Professor and Head of Toxinology at the Women's and Children's Hospital, Adelaide, Australia. He has been treating cases of envenoming since he graduated from the University of Adelaide Medical School over 40 years ago and in 1990 was invited to found the Toxinology Dept., WCH. Author of hundreds of papers, monographs, book chapters, and books, mostly on aspects of toxinology, he is internationally known for his work as a clinical toxinologist and has presented at many international meetings, mostly by invitation. In 1997, he co-founded the Clinical Toxinology Short Course, through the University of Adelaide, and this internationally recognized course, the only one of its type, is run every 2 years, plus mini-versions at selected medical meetings, and attracts both an international expert faculty and doctors attending from many nations. Julian has been involved in aspects of venom research and clinical research throughout most of his career. Since 1994, he has been the national consultant on envenoming for the sole Australian antivenom producer, CSL Ltd (now Seqirus), via his hospital (WCH; he is not paid by CSL/Seqirus). He has been an occasional consultant on clinical toxinology to WHO since about 1988 and to Australian Poisons Information Centres since the 1990s. A current focus of his activity is the Myanmar Snakebite Project, a large foreign aid project, funded by the Australian Government, aiming to improve outcomes for snakebite patients in that country. He is also developing a higher-level training program for clinical toxinology at the international level, through his role as Chair of the Board of Clinical Toxinology of the International Society on Toxinology

(IST); he is also Secretary of IST and is on the editorial board of *Toxicon*. He founded the Clinical Toxinology Resources Website (www.toxinology.com) in 2002. In 2015, he was presented with an award for “Outstanding Contribution to Medicine” by the Australian Medical Association and in 2016 was made a Member of the Order of Australia (AM) for his work in clinical toxinology. Julian is married, has two adult children, and lives with his wife in the Adelaide Hills, when not traveling overseas to meetings.

Medical toxicology is a medical subspecialty focusing on the diagnosis, management, and prevention of poisoning and other adverse health effects due to medications, drug overdose, acute drug abuse problems, chemical exposures, occupational and environmental toxins, biological agents, and envenomations. Critical care is the specialized care of patients whose conditions are life-threatening and who require comprehensive care and constant monitoring, usually in intensive care units. The disciplines of critical care medicine and medical toxicology have been intertwined throughout medical history. Texts combining the principles of these closely related specialties may be traced to medieval times; Maimonides wrote his *Treatise on Poison and Their Antidotes* in 1198 [1]. In his *Treatise*, Maimonides outlined the classification, diagnosis, and antidotal therapy of poisonings and described some resuscitation methods of the age. He also, in undoubtedly what was among the first attempts to evaluate therapies critically, refuted many of the then-popular treatments. The need to continually reevaluate – and commonly refute – generally accepted therapies continues to this day. This book continues this tradition in the spirit

established by Maimonides, except, of course, with a more data-driven approach.

Descriptions of the use of specific antidotal therapy dates back to Homer's *Odyssey*, in which Ulysses was advised to use "moly," likely a natural cholinesterase inhibitor, to treat poisoning from anticholinergic plants such as *Datura stramonium* [2]. Other publications from ancient times addressing the use of poisoning therapies include Nicander's *Alexipharmaca*, or "that which keeps off poisons"; Dioscorides' *Materia Medica*; and Galen's *DeAntidotis* and *De Theriaca ad Pisonem* [3, 4].

The identification, diagnosis, and therapy of poisons began in Greek and Roman times, with classifications by Dioscorides of poisonings by source and speed of action [3]. The Greek Nicander and King Mithridates of Pontus described the use of "theriacs" and "alexipharmacas" as universal antidotes and red clay ingestion or induction of emesis with feathers or oil to prevent toxin absorption [3]. In addition to his general description of poisons, Maimonides suggested emesis by ingesting oil, water, and honey [1]. Antimony salt, also known as tartar emetic, was widely used to induce stomach emptying and functioned as a sedative and cathartic in the nineteenth century, but it was replaced in the early twentieth century by saltwater emetics, mustard powder, mechanical throat stimulation, copper sulfate, and apomorphine [5, 6]. Ipecac syrup was first employed to induce emesis in the seventeenth century and became the emetic of choice in the twentieth century. Gastric lavage was first advocated by Munro in 1769 and supported by the physicians Physik of Philadelphia, Jukes of Britain, Dupuytren of France, and Bryce of Edinburgh [7]. In the sixteenth century, Paracelsus emphasized the fundamental importance – and to this day, the often overlooked – dose relationship of chemicals and drugs and the need for scientific study of toxins. Charcoal to adsorb toxins was described in the eighteenth century and employed in self-experiments by Bertrand and Touery, who publicly ingested toxins followed by a dose of charcoal [8]. The "universal antidote" of magnesium oxide, tannic acid, and activated charcoal was touted as the definitive adsorbent of toxins

throughout the twentieth century, until it was recognized to be inferior to activated charcoal alone [5]. Activated charcoal ultimately replaced other means of gastric decontamination beginning in the 1970s [8].

Textbooks establishing medical toxicology as a unique scientific specialty began to appear in the nineteenth century, with the publication of Orfila's *Traite des Poisons* in Paris in 1814, which emphasized experimental and forensic toxicology, followed by his student Christison's writing the first of several editions from Edinburgh of *Treatise on Poisons* in 1829 [9]. Christison reportedly first highlighted the lifesaving properties of artificial respiration in opium poisoning, showing the close relationship between medical toxicology and critical care medicine [7] (Fig. 1). Other texts of that era were Costill's *A Practical Treatise on Poisons* and Taylor's *On Poisons*, both published in 1848. Early texts of the twentieth century on clinical toxicology include Leschke's *Clinical Toxicology*; Driesbach's *Handbook of Poisoning*; Gleason, Gosselin, and Hodge's *Clinical Toxicology of Commercial Products*; and Jay Arena's *Poisoning*. Historical toxicology reference texts are listed in Table 1.

More specific therapies and antidotes to treat poisonings also date back in history. Beginning with Maimonides, some examples include the use of natural anticholinesterase inhibitors to treat anticholinergic poisoning, *Strychnos nuxvomica* (strychnine) as an arousal and emetic agent, and in the 1800s the use of rabbit brain to protect against *Amanita phalloides* mushroom poisoning [1, 6]. Physostigmine, an anticholinesterase inhibitor from the Calabar bean, reportedly was advocated for atropine poisoning by Christison's successor to the Chair of Medical Jurisprudence in Edinburgh, Thomas Fraser [7]. Arousal of the patient affected by opiate or sedative toxicity was popularized in the nineteenth and twentieth centuries, first by mechanical stimulation and later by the use of analeptics [7]. The latter included natural agents, such as caffeine, strychnine, cocaine, camphor, picrotoxin, and lobeline, and later synthetic agents, such as pentylenetetrazol, nikethamide, methylphenidate, and bemegride [10]. The use of analeptics eventually was

recognized to cause serious complications, such as hyperthermia, seizures, delirium, and increased mortality [10]. One of the most important advances in medical toxicology occurred in Scandinavia in the 1940s, when intensive supportive care with mechanical ventilation and cardiovascular support instead of analeptics was shown to reduce mortality from barbiturate poisoning from 20% to 2% [9, 10]. The overlap of critical care medicine and medical toxicology again was

reinforced. This overlap further included the advocacy for poisoned patients of close observation and monitoring; airway protection; frequent pulmonary toilet; and careful attention to fluid and electrolyte balance, cardiovascular status, and position changes.

Later advances in toxicology in the twentieth century included the discovery of the opiate antagonists/agonists nalorphine and levallorphan and the pure antagonist naloxone, the

development of highly specific and sensitive assays for drugs and chemicals, greater understanding of pharmacokinetic principles, refinement of the principles of urinary pH manipulation to enhance drug excretion, and implementation of extracorporeal removal techniques. In the twenty-first century, progress has been made in the application of immunotherapies as antidotes, the development of additional antidotes to reverse specific drug effects, the use of lipid infusion and hyperinsulinemia-euglycemia therapies, the wide availability of toxicology information via computer software and the Internet, and the early use of toxicogenetics to determine individual variations in responses to toxins and treatments. The most important advance has been the increasing number of medical toxicologists providing bedside care.

Epidemiology

Incidence

Poisonings has become an epidemic worldwide, and since 2008 has been the leading cause of injury death in the United States, exceeding those from motor vehicle deaths and falls (Figs. 1 and 2) [11].

Since 2000, the rate of deaths from drug overdoses has increased by 137%, including a 200% increase in the rate of deaths involving opioids [12]. In 1999, poisoning deaths numbered 12,986, increasing to 20,950 in 2004, 38,851 in 2013, and to an astonishing 47,055 in 2014 [11–13] (Table 2). This represents an incidence of poisoning deaths of 4.4 per 100,000 population in 1999, to 7.1 in 2004, and to 14.7 in 2014. Of the 47,055 drug overdose deaths in 2014, 28,647 (61%) involved some type of opioid, including heroin (Fig. 3) [12]. Most drug poisoning deaths occur in those between the ages of 25–64, with the highest rate in the 45–54 age group (Fig. 4) [14]. In the United Kingdom, there is a reported incidence of 310 poisonings per 100,000 population, or 170,000 annual hospital visits, much lower than the US rate [14, 15]. Overdoses account for one fourth of all suicide attempts in England [16].

Hospital Visits

Poisonings typically represent 1–3% of all emergency department visits and account for 10% of all admissions for injuries [17, 18]. Reports of emergency department (ED) visits for poisonings in the United States range from 1.1 to 2.5 million per year, depending on the source, data collection methods, and definitions [19, 20]. The peak age

Fig. 2 Motor vehicle traffic, poisoning, and drug poisoning deaths rates: United States 1980–2008. From the US National Center for Health Statistics Data Brief. 81: December 2011

for ED visits for drug poisoning is 20–34 (Fig. 5). Hospital admissions for poisonings in the United States are about 130 per 100,000 population, or about 260,000 poisoning admissions in the United States each year [20, 21]. There are a reported 80,000 poisonings admissions each year in England, which result in about 400 deaths, or 0.5% of all such admissions [16]. According to another report, for all of the United Kingdom, the total admissions are about 170,000 annually [15]. It was reported in 2012 that drug-related

admissions in England alone increased by 58% from 2000 to 2001 [22].

Emergency department reporting of poisoning cases is highly variable. In one study, an academic tertiary care emergency department called its regional poison control center (PCC) on 26% of its cases [19]. In many poisoning cases, the exposure was highly reported to the PCC (e.g., 95% for cyclic antidepressants), in contrast to cases of drug abuse (e.g., 5% for cocaine or heroin poisoning), which are not often reported to poison control centers. A review of an entire state’s hospital admissions for poisoning indicated that the Oregon Poison Center was contacted for 54%, or 1,352, of 2,486 admissions in 1989 [23].

Drug overdoses typically account for approximately 2.5–5% of all intensive care unit (ICU) admissions in the United States, with an average length of stay (LOS) of 2.5–3.5 days [24, 25]. Poisonings have been reported to represent 11–14% of all ICU admissions in some countries [26–28]. In the 2014 annual report of the National Poison Data System of the AAPCC, 101,141 of the recorded 612,184 patients (16.5%) referred to a hospital were admitted to an ICU [29]. This number of annual US admissions to an ICU can be estimated to be only about one half of all ICU poisoning admissions, based on underreporting of cases to regional poison centers [19, 20]. Mortality

Table 2 Causes of death in the U.S. for 2013

Mortality 2013
All unintentional injury deaths
Number of deaths: 130,557
Deaths per 100,000 population: 41.3
Cause of death rank: 4

rates in the ICU for poisoning admissions range from 3 to 6% according to most reports [24–28].

Toxins

The history of drugs and toxins causing hospital admissions have evolved over the last several

decades. It is interesting to review historically these changing patterns. Reports from Edinburgh describe the changing patterns of admissions from the 1960s into the 1990s. In 1966, 60% of the admissions to the Royal Infirmary of Edinburgh were for barbiturate poisoning [30]. Only in the teenage group did aspirin surpass barbiturates as a cause of toxicity. In this time period, poisoning

accounted for 10% of hospital admissions. In 1968, 74% of the patients had a LOS of 2 days or less [31]. Proudfoot reported on the subsequent 20-year trend (1967 through 1986) at the same center [9]. During this period, barbiturate poisonings decreased from 30% of admissions in the 1970s to a rare occurrence. Methaqualone was initially responsible for 10% of admissions but by the mid-1970s was almost no longer seen. A predominance of benzodiazepine overdoses subsequently replaced barbiturates and methaqualone, their incidence increasing from 10% to approximately 40% of admissions in the 1970s. Throughout the 1970s, there was also a rapidly increasing admission percentage for paracetamol (acetaminophen), whereas there was a decreasing trend for salicylates.

Benzodiazepines were reported as the predominant ICU admission for poisonings in Stockholm, Sweden, from 1972 through 1985, increasing from 17% to 28% of the total number [32]. In 51% of these cases, a benzodiazepine was part of a polydrug overdose and in 21% of cases, benzodiazepines were the single ingestant. Benzodiazepine-alone admissions were intubated in 37% of cases, whereas the intubation rate was 47% if benzodiazepines were consumed with alcohol or as part of a polydrug overdose. Of the 702 ICU admissions, the complication rate was 9.8%. There were five fatalities related to respiratory insufficiency or aspiration pneumonia or both.

During the 1980s and 1990s, cyclic antidepressant poisoning was a predominant ICU admission diagnosis. In the Netherlands from 1994 through 1998, cyclic antidepressants constituted 33.3% of the total intoxication admissions and 2.4% of total admissions. The average LOS was 3.1 days. Of these patients, 40% were intubated and seven (2.7%) died [26].

In New Zealand in 1992, there was a similar experience [33]. Of all emergency department visits, 1.2% were poisoning related, yet these cases constituted 11% of ICU admissions. The incidence was 17 per 100,000 population. The most common agents ingested were cyclic antidepressants (19.6%), benzodiazepines (18%), acetaminophen (16.9%), and various antipsychotics [33]. The average LOS was 2.4 days. A 6-year review (1986 through 1991) of ICU admissions

for poisoning was published in Australia [27]. Poisonings accounted for 13.8% of all admissions. The most common agents were benzodiazepines, ethanol, tricyclic antidepressants, acetaminophen, phenothiazines, and antihistamines. The mean age was 32, the mortality rate was 2%, and 6 of the 14 fatalities were from nonmedicinal products [27].

The introduction of flumazenil, a benzodiazepine antagonist at the γ -aminobutyric acid receptor site, reportedly had an impact on ICU care and LOS in Israel. Leykin and colleagues described acute poisonings treated in the ICU from 1982 through 1984 [34]. The predominant intoxicants were benzodiazepines (51%), tricyclics (25%), barbiturates (21%), and narcotics (11%). Flumazenil was believed to have contributed to a decreased ventilator time and LOS (from 4.8 to 3.1 days). The introduction of the safer antidepressants, selective serotonin reuptake inhibitors, also markedly reduced the ICU admission rates, LOS, and cost of care [35].

In many countries, nonmedicinals such as plants and pesticides remain a significant cause for ICU admissions and fatalities. Over a 15-year period in Hong Kong during the 1980s and 1990s, rates of medicinal poisoning admissions per 100,000 population ranged from 57.3 to 80.9 [36]. In the more recent years of the report, admissions for nonmedicinal poisonings decreased from 53 to 22 per 100,000 population. Overall, poisoning fatality rates have ranged from 2 to 4 per 100,000 population, with an increasing rate into the 1990s.

The climate can have an impact on environmental exposures. In South Africa, 15.5% of toxicology consultations are for plant, spider, snake, scorpion, mushroom, and insect poisoning [37]. In addition, frequent consultations occur for household, agricultural, and industrial agents, including cholinesterase inhibitors and other pesticides, volatiles, corrosives, and soaps. The pattern of pharmaceutical exposures is similar to that in many other countries, however. Acetaminophen is the most common (14.6%), followed by benzodiazepines (13.1%), aspirin and nonsteroidal antiinflammatory drugs (9.4%), antidepressants (6.7%), and cardiovascular agents (5.5%) [37].

In a report from Ecuador, only 26% of the reported poisoning cases were drug related [38]. The leading drugs were benzodiazepines (24%), acetaminophen (23%), aspirin (22%), and carbamazepine (11%). Except for carbamazepine, this experience is not too different from that in many other countries. The top four categories of nonmedicinal substances were organophosphate pesticides, which constituted 18% of all poisonings, followed by phosphorus (14%), rat poison (10%), and solvents (6%). Pesticides are often a leading category of poisoning in some developed and many underdeveloped countries. In one hospital in Turkey, pesticides followed analgesics as the second most common poisoning [39].

A few reports have focused on pediatric poisoning admissions. In a study from Boston during 1981 and 1982, 90 acute poisonings (52 accidental and 38 suicidal) constituted 1.1% of the 8,296 total admissions [40], 64% were medical ICU admissions and 4.5% of the total medical ICU admissions. The average LOS was 2.2 days. There was one fatality due to diphenoxylate. The most frequent agents responsible were alcohol (11), barbiturates (9), cyclic antidepressants (9), theophylline (8), aspirin (8), and benzodiazepines (8). A review of pediatric hospitalizations from the same children's hospital approximately a decade later (over a 4-year period from 1992 to 1995) documented a 0.9% admission rate for poisoning [41]. Two thirds of the 638 admissions for poisonings were medication related. Toddlers, age 1–5 years, accounted for 42% of admissions, and adolescents older than 12 years accounted for 45% of admissions. In the toddlers, lead, caustic agents, and benzodiazepines were the most common agents, whereas acetaminophen predominated in the adolescents. Antidepressants, antihistamines, and salicylates also accounted for a significant number of admissions. The LOS over this period decreased from 5.85 to 3.45 days [41].

The US state of Washington reviewed all hospital pediatric discharges over an 11-year period [42]. The incidence was 45 per 100,000 children per year. Intoxication accounted for 0.6% of the hospitalizations. Children aged 12–18 accounted for 75% of the admissions, whereas toddlers (age ≤ 5 years) accounted for 20% of the admissions. The

fatality rate was 0.2%. The average LOS was 1 day (range 1–3 days). ICU issues related to pediatric poisoning are discussed in detail in Intensive Care of Pediatric Poisoning Patients.

Currently, the best source for identifying the poisons, toxins, and toxidromes likely to cause hospital admissions is the ToxIC (Toxicology Investigators Consortium) Registry of the ACMT (American College of Medical Toxicology). Although the cases collected are less than the National Poison Data System of the AAPCC (American Association of Poison Control Centers), they better reflect those patients requiring inpatient care by medical toxicologists and intensivists. In 2014, 9,712 cases were entered from 47 medical toxicology services, providing care at 77 clinical facilities [43]. They included 81% of the accredited US medical toxicology fellowship sites, thus capturing the great majority of patients seen at the busier academic medical toxicology facilities. There is likely a bias in this data towards the sickest poisoned patients based on the type of facility and the active presence of a medical toxicology program. The ToxIC Registry recorded the referral services leading to admissions or inpatient consultations and found that almost all (93.5%) came from the emergency department, the admitting inpatient service, or by transfer from another facility [43]. Of concern was that only 0.1% of cases accounted for referral from a poison control center to a medical toxicology service, demonstrating a current lack of collaboration between poison centers and medical toxicology services. This presents a heretofore underutilized opportunity to greatly improve patient care by coordinating initial phone consultations with bedside care by toxicologists.

Pharmaceutical products exposure, particularly intentional, was the most common reason for consultation by a medical toxicologist, accounting for 61.7% of all cases. Accidental exposures to pharmaceuticals or toxins followed with 13.4% and organ system dysfunction at 3.8% [43] (Table 3). Adverse drug reactions represented only five of the total cases for medical toxicology consults, yet are increasing events which could benefit from medical toxicologist consultation. This demonstrates the need for collaboration

category of individual psychoactive drugs of abuse, the rapid emergence of synthetic cannabinoid abuse accounted for 26% of these agents, second only to herbal marijuana (32.4%) in this class.

The treatment required by the patients in the 2014 ToxIC Registry clearly exemplify the intertwined relationship between medical toxicology and critical care medicine. Of the 9,172 patients, antidotes were administered 2,962 times, or 51.8% of all treatments reported [43]. *N*-Acetylcysteine for acetaminophen overdoses and naloxone or nalmefene for opioids accounted together for over one half (51.5%) of all antidotes administered. The only other antidote given that was more than 10% of the total was sodium bicarbonate, usually used for cardiac conduction abnormalities, arrhythmias, or hypotension in sodium-channel blocker toxicity (Table 5). Specific toxicologic care was administered in conjunction with supportive general pharmacologic and nonpharmacologic care, frequently directed by intensivists. General pharmacologic supportive care was given 2,843 times, with benzodiazepines, opioids, and vasopressors being the most common (Table 6). Intravenous fluid administration and mechanical ventilation were the most commonly employed forms of supportive care, used 2,733 times collectively in the 9,172 patients (Table 7). The provision of critical care and medical toxicology together, either by the medical toxicologist or in collaboration with the intensivist, is essential for the recovery of the poisoned patient.

Fatalities by Toxin

Carbon monoxide (CO) is the second most common toxin causing poisoning fatalities, with alcohol the leading cause [45]. Most CO fatalities do not present to health care facilities but rather are found deceased and are coroner cases. Historically, in the 1950s and 1960s in Scotland, England, and Wales, barbiturates were the second most common

cause. In 1962, there were 4,208 carbon monoxide deaths and 1987 barbiturate, sedative, and salicylate deaths combined [30]. In 1968, the fatality rate for all poisoning admissions at The Royal Infirmary of Edinburgh was 0.7% [31].

The Rhode Island Poison Center reviewed and compared its fatality reports with reports of the medical examiner for a 4-year period (1986 to 1989) [46]. Carbon monoxide was the most common cause of fatality, accounting for 98 of the 369 fatalities. After excluding cases of patients pronounced dead at the scene or dead on arrival, there were 112 cases in which the PCC could have been called; however, they were called on only 33 of these cases. In 10 of these cases, the poison center determined that they would have had additional recommendations that may have altered the outcome.

In Australia, deaths due to poisonings in 1989 and 1990 [47] had an average victim age of 36 years. Opiates primarily accounted for 40% of the cases, cyclic antidepressants accounted for 14%, and benzodiazepines accounted for 6.5%. Only 25 of the 231 patients reached the hospital alive. In a later Australian report, the Hunter Area Toxicology Service reported a 0.6% mortality rate from 1987 to 1995 [48].

Recent data show that most poisonings who are now admitted to a hospital have a low fatality rate. Hospital fatality rates in both the National Poison Data System of the AAPCC and the TOXIC Registry of the ACMT are about 1% in the years 2012–2014 [20, 43]. Currently, the most common causes of death in poisoned patients presenting to a hospital are pharmaceuticals, causing 83% of all deaths. Analgesics, and specifically opioids and acetaminophen, accounted for 39% of all deaths [20, 43]. Prescription opioids as a class were the most common, particularly methadone, followed closely by oxycodone and hydrocodone. However, illicit heroin was the single most common cause of death. From 2000 to 2014, there has been a 200% increase in opioid deaths, particularly heroin (Fig. 6).

Stimulants such as amphetamines and cocaine were the second most common cause of in-hospital deaths, followed by cardiovascular drugs, antidepressants, and sedative/hypnotic/antipsychotic agents [20].

Fig. 6 Opioid deaths by class, 2000–2014 From Ref. [12]

Aspiration syndrome after drug overdose is a common complication and reason for ICU admission. In a study from 1987 through 1995, 39% of all community-acquired aspiration syndromes admitted to the ICU were secondary to drug overdose [49]. The overall mortality rate was 22%, but it was unclear how many of these fatalities followed drug overdose.

The aforementioned reports show that poisoning fatalities, mostly suicidal, continue to be a leading cause of death, especially in young adults. In North America, most of these fatalities occur out of the hospital and are reported by coroners. In-hospital fatalities continue to occur, however. Although some deaths are unavoidable (e.g., post-cardiac arrest or hypoxic brain injury occurring before hospital arrival), avoidable deaths still occur. A validated assessment or predictive tool for poisoned patients does not exist. It is difficult to envision the development of such a tool because of the variability of each potential intoxicant and the diverse pharmacokinetic profiles of drugs and other chemical substances. The time of ingestion and dose taken can be used to predict the course of intoxication. This evaluation must be done individually in each case, however. The medical toxicologist and PCC are resources to help predict severity for each individual case and to provide specific information that may attenuate the severity.

The mental health and social issues that lead to poisoning fatalities need further studies and resources to help reduce poisoning fatality rates.

Stern and associates [45] followed 104 consecutive ICU admissions for poisonings [50]. Of these, 88 were followed for 5–24 months. The follow-up mortality rate was 6% by another overdose; 42% were readmitted for another overdose or psychiatric illness.

Ojehagen and colleagues [46] analyzed the repeat overdose patients and the nonrepeaters in a total of 79 patients admitted to a Swedish ICU over an 18-month period [51]. The predominant psychiatric diagnoses were adjustment disorder (31%), alcohol abuse (22%), major depression (19%), dysthymia (14%), and psychosis (9%). Of the patients, 66% were receiving psychiatric care. Repeaters were 58% of the sample and were less educated, had a higher rate of unemployment, and were more likely to be taking psychopharmacologic therapy. In many other series of patients from other countries or regions, the rates of repeaters have been much lower. The psychiatric care of critically poisoned patients is discussed in greater detail in ► [Chap. 6, “Psychiatric Issues in the Critically Poisoned Patient.”](#)

Medical Toxicology Training

Training of health care professionals in toxicology has lagged behind that of other disciplines around the world [52]. Academic toxicology programs are lacking in most countries, although veterinary and pharmacy students receive some background

in the field [52, 53]. It became apparent in recent years in the United States that the fields of emergency medicine, critical care medicine, internal medicine, pediatrics, pharmacology, and occupational medicine could collaborate their basic and clinical science curricula to train physicians in the subspecialty of medical toxicology [54]. Success has been limited so far, owing to inadequate resources in faculty, curriculum guidelines, and clinical training centers. Despite this, in the United States there is a clearly evolving trend of medical toxicology training for medical students, residents, and fellows, particularly at those institutions with medical toxicology attendings.

Medical Students

A 1990 survey of Canadian and US medical schools found that although 88% of US schools reported teaching medical toxicology, only 5% had formal toxicology courses [52]. In Canada and the United States, medical schools averaged only 5 h of didactic toxicology teaching. An MD or PhD toxicologist was on staff at only 51% of the schools. This report represented an improvement, however, from an earlier survey of undergraduate US education [55]. In Great Britain's 24 medical schools, 22 reported formal toxicology teaching for a median of 5 h (range 1–12 h) [56]. Many medical schools have moved away from traditional lecture-based curricula to problem-based, facilitator-guided learning formats. Toxicology is often covered in the neuroscience or pharmacology block in the second year [57].

Residency Training

The experience in medical toxicology obtained in residency programs is highly variable. The formalization of training in medical toxicology varies greatly among countries. In the United States, medical toxicology is a core content area for emergency medicine residencies, so these postgraduate programs provide the most training in the field. Nonetheless, only 26% of the programs in a 1990 survey of US emergency

medicine residencies had a board-certified medical toxicology faculty member and 19% offered no toxicology rotations at all [58]. Of the programs, 43% required toxicology training outside of the emergency department, but most of this was at poison information centers rather than bedside experiences. A 2,000 survey of emergency medicine residencies documented an increase in toxicology faculty to 63% of the programs [59]. A toxicology rotation was required at 76% and was an elective at 19%. The experience was widely variable, however, with most still receiving the training primarily at a PCC rather than inpatient care [59]. PCC training has been shown to modestly increase test scores in toxicology [60]. Poison information center experience, however, is limited in its ability to provide the skills necessary to treat critically poisoned patients.

In other US residency training programs, clinical toxicology education is usually lacking any meaningful experience. Only 4% of pediatric and psychiatry programs offer a clinical toxicology rotation, yet only 11% of the pediatric residency directors believed that their residents needed improvement in toxicologic management [61, 62]. Only 41% of psychiatry programs have didactics in toxicology, and only two programs had a toxicology elective [62]. Although internists in their roles as hospitalists, admitting physicians, or intensivists care for most poisoned inpatients, there is no toxicology required in internal medicine residency programs except substance abuse didactics.

Fellowship Training

In the United States, medical toxicology is a formally recognized subspecialty by the American Board of Medical Specialties, the regulatory authority for specialty and subspecialty certification. Postresidency fellowship training programs in medical toxicology emerged in the 1970s in the United States. In 1974, the American Board of Medical Toxicology (ABMT) was established by a subgroup of physician members of the American Academy of Clinical Toxicology (AACT) to set standards in care and training [54]. The primary

function of the ABMT was offering a certifying examination in medical toxicology to physicians, which began in 1975. Entrance to this exam required completion of a fellowship program or a practice pathway of 2 years of clinical experience. In 1989, the ABMT published guidelines for fellowship training in medical toxicology and continued to certify physicians until 1992, when the American Board of Medical Specialties officially recognized medical toxicology as a subspecialty [63]. This new subspecialty board was developed and sponsored by the American Boards of Emergency Medicine, Preventive Medicine, and Pediatrics [54].

Medical toxicology fellowship training requirements in the United States have been developed under the auspices of the American College of Graduate Medical Education (ACGME). Board certification or qualifications are required in a primary medical specialty, and subspecialty medical toxicology training requires 2 years of full-time fellowship in a program accredited by the ACGME. Medical toxicology program requirements are found at www.acgme.org. Fellowship programs grew from 21 in 1997 to 28 in 2016, with 70 fellows in training (www.acmt.net) [64]. The certification examination was first offered in 1994, and accreditation of training programs began in 1999 [64]. In 2000, the grandfather practice route to medical toxicology subboard certification closed. Qualifications to be entered into the ABMS subspecialty examination now require completion of an approved 2-year fellowship. Cognitive expertise examinations are also now required, and a recertification examination is required every 10 years. The core content of medical toxicology, which outlines the knowledge base essential for the practice of medical toxicology, fellowship training, and the framework of the certification and cognitive examinations, was updated in 2012 [64]. The core content includes principles of toxicology, toxins and toxicants, clinical assessment, therapeutics, population health, and analytical and forensic toxicology.

Clinical experience is still variable and often very limited in many programs, despite an ACGME requirement for providing bedside evaluation and management of toxicology patients for

a minimum of 12 months. Some programs offer little but the required experience in telephone consultations at a regional poison control center. Bedside experience, although often limited, usually includes consultations on adult and pediatric patients. A few programs have inpatient admitting referral services, but most are consult services. Limitations on bedside training at many fellowships continue to restrict expansion of the specialty and expertise of recent fellowship graduates. In the only study of fellowship training, it was reported that fellows spent only 19% of their time in inpatient encounters. The fellowship programs had a mean total exposure to only 204 (Range 5–1,000) inpatients per program annually [64]. Twenty-four percent of all fellows were required to work in the ED as a part of their fellowship, further diluting their inpatient toxicology experience [64]. Pediatric emergency medicine offers a combined fellowship with medical toxicology [66, 67]. In the United Kingdom, medical registrars receive training in medical toxicology at regional poison treatment centers, in preparation to be consultants in the specialty [9]. They receive extensive bedside experience in the diagnosis and treatment of the poisoned patient, typically well beyond that of fellows in US programs.

With the establishment of the medical toxicology subboard by the ABMS, the American Board of Medical Toxicology (whose primary purpose had been to provide the certifying examination) was no longer necessary and went out of existence, although the ABMT Certification remains a lifetime board certification. The ACMT was founded in 1993 to fill the void left by the dissolution of the ABMT and to provide a physician specialty society for medical toxicologists. Since that time, the College has continued to expand both in numbers and activities, including offering an annual scientific meeting and other educational seminars, publishing the *Journal of Medical Toxicology*, providing a voice in organized medicine for toxicologists, providing research and training grants, and sponsoring the Toxicology Investigators Consortium Case Registry (www.acmt.net). The College now represents the vast majority of physicians who are Board-Certified in Medical Toxicology. By 2016, there were over

500 members of the ACMT, who were certified by the ABMT or the ABMS subspecialty board. Of these, 221 ACMT members had been recognized as Fellows of the American College of Medical Toxicology (FACMT), meaning they were not only board-certified but also had made significant contributions to the specialty (www.acmt.net).

Medical Toxicologists

Medical toxicologists admit or consult on patients hospitalized or in the ED, staff outpatient occupational and environmental practices, perform research and education, serve industry or governmental agencies, participate in pharmacy and therapeutics committees, and serve as expert witnesses. Most often, however, they still practice by providing telephone consultation for a PCC [68]. There were 209 physician toxicologists certified by the ABMT between 1974 and 1992, having qualified by fellowship training, practice experience, or a combination of both, but by 1992 there were only 183 still practicing in this field [64, 68, 69]. Between 1994 and 2014, 498 medical toxicologists were certified by the ABMS subboard, although 60 certifications have since lapsed. In terms of professional practice, a survey of medical toxicology fellowship graduates in 1998 found that fewer than half spent more than 50% of their professional time in medical toxicology at that time, and one third spent less than 25% [64, 69]. In 2002, there were 315 medical toxicologists, representing 55 solo or group practices serving 125 hospitals in the United States [70]. The average number of in-hospital patients treated annually at that time was 228 per group practice, and 36 of these groups were affiliated with a poison control center. A later survey in 2007 showed that 88% of the respondents were clinically active in toxicology, but only 35% spent an equal or more time in toxicology as compared to their primary specialty [68]. Only 22% saw more than 200 acetaminophen-poisoned patients per year, the most common poisoning seen, and 46% saw less than 50 per year. Of the estimated 260,000 poisoning hospitalizations in the United States each year, only about 12,540 (<1%) are seen

by a medical toxicologist. [64, 69–71] Most critically poisoned patients are cared for not by medical toxicologists but by intensivists, hospitalists, or primary care physicians. A barrier to medical toxicology practice has been perceived to be inadequate financial reimbursement. In the early years of the specialty, this was indeed true for most toxicologists. In one study of a solo practice, charges and income were nominal [72]. As the specialty evolved, multiple practices nationally began to succeed in becoming economically feasible [73]. Some of the reasons were the increasing number of adolescents and adults requiring hospitalization due to drug abuse or intentional self-poisoning, increasing complexity and severity of cases, changes in practice methods from telephone consults to bedside care, the increased number of medical toxicologists available to form practice groups, and gradually increased knowledge of these groups in billing practices. Nevertheless, adequate compensation for medical toxicologists is a persistent problem because of the poison control center model of telephone consultations provided with little or no charge [74].

Other Health Care Professionals

Additional training in medical toxicology is needed for other health care professionals worldwide. Critical care and emergency department nurses scored only about 50% on a questionnaire about antidote dosing and indications [75]. Paramedic training programs in the United States devote only 2% of their time to toxicology, and only 11% have a designated experience at a poison center [76]. Poison centers and regional toxicology treatment centers are rich resources for continuing education for health care professionals. These centers have filled this role in industrialized nations and in developing countries, such as Zimbabwe [77]. The poison center may function as a multidisciplinary training site where medical, pharmacy, nursing, paramedic, and school of public health students work together with residents and toxicology fellows in the delivery of clinical advice [78]. Clinical pharmacology

has been combined with clinical toxicology in some institutions [79].

Medical Toxicology Practice Standards

The provision of poisoning treatment throughout the world generally is the responsibility of emergency physicians, pediatricians, internists, occupational physicians, and intensivists. They are supported by a relatively small group of trained clinical toxicologists, consisting of medical toxicologists and pharmacologists, who usually are located at large academic centers or poison centers. In such centers, a medical toxicologist often functions as the primary attending physician for poisoned patients. In the absence of locally available specialists in the field, physicians are forced to rely on telephone consultation, computerized data information systems, or standard texts. The now-disbanded World Federation of Associations of Clinical Toxicology Centers and Poison Control Centers in the 1960s advocated that poison information centers be available and provide the physician with advice tailored to the individual case, but this is not always practical [9]. The American College of Emergency Physicians (ACEP) has stated that poison treatment and information should include consultation with a medical toxicologist or PCC and that there should be regional centers for poison treatment for serious poisonings [80]. Many professional societies, such as the AACT, the European Association of Poison Centres and Clinical Toxicology (EAPCCT), the Society of Critical Care Medicine, the ACEP, and the American Heart Association, have published clinical guidelines for the treatment of poisonings, and these principles are outlined in chapters throughout this book [81–83].

There are multiple demonstrated weaknesses in providing poisoning care with the frequently employed model of care by generalists, such as lack of available medical toxicology care or consultation. Treatment recommended by emergency departments in simulated cases of drug overdoses was found to be correct in only 68% of cases. This included only 50% correct treatment of cases presenting to a teaching hospital and in only

22% of cases when the emergency physician was consulted [84]. A study of poisoning deaths in Massachusetts found that 29 of 60 deaths (48%) had errors in management as judged by an expert panel [85]. In two other studies, it was judged that 20–24% of in-hospital poisoning deaths could have been prevented if a medical toxicologist had been consulted [46, 87]. In England and in the United States, one fourth of all poisoning deaths occur after hospitalization, suggesting that better prehospital or in-hospital care might prevent some of them [85, 87]. An evaluation of the Acute Physiology and Chronic Health Evaluation (APACHE) III showed APACHE III to underpredict drug overdose mortality [88]. In this observational cohort study, APACHE III was used to predict mortality for 1,032 drug overdose admissions to 161 US hospitals. The predicted mortality from APACHE III was 7 (0.7%), but the actual mortality was 25 (2.4%) ($P < 0.0001$). This study suggests that in-hospital poisoning deaths are a greater risk than the APACHE III score can predict, or that there is need for improvement in toxicologic care.

A report from England showed significant variability in the management of poisoned patients. Thomas and coworkers reported this finding by comparing six hospitals in northeastern England over 12 weeks [17]. The catchment area included 1.52 million people. The admission rates for patients presenting to the accident and emergency wards varied from 50% to 87% (average 73%). The LOS varied from 0.8 to 2.1 days. Reasons for this variability were not presented. Only 12% of the patients had an LOS greater than two nights. Being elderly and ingesting benzodiazepines, acetaminophen, or antidepressants seemed to predict a longer LOS. Of the 690 admissions, there were three fatalities (0.4%) [17].

One study has now demonstrated that bedside care by medical toxicologists reduces lengths of stay, cost, and mortality of inpatients as compared to care by nontoxicologists. In this 2-year study of 3,581 patients, the LOS for the patients admitted to a large group's toxicology service were 0.3 days shorter than patients treated by nontoxicologists at both the same and different hospitals. This resulted in a median savings of 1,483 hospital days and

4,269 million dollars [89]. Most importantly, mortality rates were statistically significantly lower under the toxicologists' care, with a projected potential lives saved of 54.7 per 1,000 patients. Unfortunately, in 2014 there were only 42 reported medical toxicology services in the USA, serving 72 individual healthcare institutions [43].

Toxicology Resources

References for toxicology information in the mid-1900s were card files of individuals, poison centers, and the US National Clearinghouse for Poison Control Centers, followed by a computerized version of the Clearinghouse cards [78, 90]. In the 1970s, microfiche technology allowed for the storage and retrieval of larger toxicology databases, which eventually were replaced by computerized information database systems, such as the POISINDEX, which has become one of the standard references for clinicians and poison centers in the United States [78]. In the United Kingdom, the TOXBASE Internet database system is available to emergency departments and individual physicians at www.spib.axl.co.uk [9]. Both database systems contain extensive information on the features and management of pharmaceuticals and toxins.

Clinical toxicology textbooks are another resource for clinicians, although their reliability has been variable. To our knowledge, none before this book has comprehensively focused specifically on critically poisoned patients. The *Physician's Desk Reference* is a frequent source of drug overdose information for 50% of US physicians according to one survey, yet it was judged to include deficient treatment recommendations in 80% of the drugs reviewed, and in 35% of the drug outlines, contraindicated or potentially harmful advice was included [91].

It is often thought that contacting a PCC provides the local physician with reliable assistance in treating poisoned patients, avoiding transfer to a specialty center; some medical organizations even recommend that this be a standard of care [92, 93]. Contacting a PCC has been shown to be useful in cases of minor poisonings and drug or toxin identification, in which PCCs gave correct

information 75% of the time in one study [94]. Physicians contact a PCC in only 19–29% of serious cases, however, and even then the recommendations are followed less than half of the time [46, 85, 95, 96]. Although advice from PCCs regarding specific poisonings is generally excellent, the pharmacists or nurses giving most consultations from PCCs are not fully prepared to advise on issues related to the care of seriously ill patients. Contacts with PCCs are increased if a physician toxicologist is available, but experts are frequently not available or accessed for individual cases, and their advice is followed in less than two thirds of these cases [95, 97]. A study of recommendations by a PCC to use two advanced toxicology therapies, hyperinsulinemia euglycemia (HIE) and intravenous fat emulsion (IFE), showed that only 31 of 70 patients (42%) actually received HIE, and in only 10 of 30 cases (33%) did the physician follow the advice to give IFE [98]. Consultations by telephone have been known to be fraught with hazard, which may account for some of this reluctance, along with unfamiliarity with such treatments. Clinical data recorded at hospitals are often unavailable to PCCs or are significantly different from that provided, and the specialist at the bedside is often in a better position to assess and act on the patient's status than a telephone consultant [9, 99]. For this reason, the ACEP states, "Most medical conditions cannot be accurately diagnosed over the telephone." [93] The ACEP further recommends that "emergency departments do not attempt medical assessment or management over the telephone." [93] The assessment of the circumstantial, laboratory, and clinical evidence requires a high level of clinical and toxicologic expertise on the part of the consultant at the PCC, who is often a nonphysician [9]. Limitations of this model of poison care delivery are exemplified by a study in which treatment advice was sought from US PCCs in a simulated case of serious antidepressant poisoning. The advice was deemed to be correct from only 42% of all the PCCs contacted and from only 60% of the regional centers certified by the AAPCC [94]. In another study, 43% of recommendations by regional PCCs for the use of two antidotes, fomepizole and digoxin FAB fragments, were

improper [100]. Regrettably, most physicians and hospitals must rely on this model of toxicology care for inpatient care due to the relatively small number of medical toxicologists in the USA.

The lack of adequate resources also hampers hospitals in providing care to poisoned patients. Pharmacy stocking of emergency antidotes has been found to be adequate in a wide range of hospitals surveyed (2–98%), depending on the antidote, but only about 1% of hospitals have adequate supplies of all antidotes in amounts necessary to treat even one patient [101, 102]. Most health care facilities have on-site access to qualitative urine drug assays for only a few drugs of abuse and must rely on distant toxicology reference laboratories for more comprehensive drug screens and many necessary quantitative analyses [70]. Specialty poisoning treatment units are available in major cities in some countries, but this is not universally true.

Sites of Care

An ICU is usually recommended to be the most appropriate location for management of poisoned patients requiring hospital admission because of the availability of rapid diagnostic procedures, intense observation and monitoring, and complex treatment modalities [103]. Over 200,000 ICU admissions are due to drug- or toxin-related causes annually in the USA [29]. Caution must be employed in triaging patients with altered mental status to other sites. One study found that 69% of patients with unrecognized medical emergencies inappropriately admitted to a psychiatric unit had a drug overdose or intoxication, or severe drug/alcohol withdrawal [104].

The Society of Critical Care Medicine recommends that overdose patients be admitted to an ICU if they have cardiovascular instability, altered level of consciousness with airway compromise, or seizures [105]. One study found that ICU admission was necessary if in the emergency department the patient required mechanical ventilation or had seizures, coma, a partial pressure of carbon dioxide greater than 45 mmHg, arrhythmias, high atrioventricular block, a QRS greater

than 0.11 s, or systolic blood pressure less than 80 mmHg [106]. The Glasgow Coma Scale has been used to predict the need for ICU admission, with a score of less than 13, intubation, or the presence of infectious, cardiovascular, or electrocardiogram complications being sensitive and specific for needing ICU interventions in one study [107]. A smaller study suggested that nonintubated patients with a Glasgow Coma Scale score greater than 6 did not require ICU admission and could be handled on the general medical floors [22]. Intensive care for poisoned patients also may be delivered in an emergency department observation unit with respiratory care capabilities and can result in fewer complications and shorter LOS compared with admission to a general medical floor [108–110].

In severe cases, local resources may be inadequate to meet the patient's needs. Transfer of seriously ill patients to specialty centers is supported in policy statements of the ACEP, ACMT, and Society of Critical Care Medicine [111–113]. Transfer is often necessary to provide access to experienced medical toxicologists, antidotes, and analytic laboratory services not available elsewhere. Specialty poison treatment centers are available in a few cities around the world (see later section on “[Poison Centers](#)”).

Recommended Equipment and Resources

Care of the seriously poisoned patient requires medical and nursing expertise, an emergency department and critical care unit, analytic toxicology laboratory support, an adequate supply of antidotes, and psychosocial services [31, 114]. Available services should include hemodialysis, a clinical laboratory able to perform routine analyses, plus at least the emergency toxicology laboratory tests listed in the ACMT facility guidelines, a 24-h pharmacy, radiology, respiratory care, and psychiatric and social services [115].

The ACEP has published a clinical policy for the care of patients with toxic exposures, including recommended laboratory tests and common necessary emergency antidotes [83]. Although

intended for facilities serving as regional poison treatment centers, the guidelines of the ACMT also outline the resources deemed necessary in any hospital caring for poisoned patients [115]. The minimal qualitative urine drug assays recommended are listed in Table 8, and the quantitative tests necessary for immediate care are listed in Table 9. In addition to these drug assays, the hospital laboratory must be able to perform rapidly arterial blood gases, a comprehensive metabolic panel, coagulation studies, serum ammonia, serum osmolality, acetone, and lactate.

Antidote needs may vary based on geography and setting; the minimal required antidotes are listed in Table 10.

Poison Centers

The proliferation of accidental and intentional poisonings in the 1940s led to the development of centers for poison information dissemination and treatment around the world. The infancy of such centers was in Copenhagen, the Netherlands, Edinburgh, and Chicago. These specialty centers serve as resources for poison information, public and health professional education, poison prevention, research, and in some cases tertiary patient care. The increasing number of childhood accidental poisonings and deaths and physicians'

general lack of knowledge and resources about drug and chemical ingredients initially highlighted the need for poison centers.

Poison Information Centers

The first poison information service is thought to have been established in the Netherlands in 1949, followed in Europe by similar centers in Paris in 1959, London and Edinburgh in 1962, and Zurich in 1966 [9, 53]. The first information center, or PCC, in the United States was established in Chicago in 1953 and had been preceded by an informal information service in the pharmacy of St. Luke's Hospital [90]. The first PCC was intended to provide information to physicians on ingredient and toxicity information, and the database was a set of small cards. Subsequently a manual was developed outlining the ingredients of common household products and distributed to emergency departments. Similar centers began to appear across the United States, and by 1957, there were 17 PCCs, which now also were taking calls from the public [90]. An initial barrier was the lack of reliable data sources and data collection, so the US Surgeon General designated the National Clearinghouse for Poison Control Centers, which distributed index cards of poison information and collected poison data from centers [90]. There was an uncontrolled growth of PCCs in the United States during the 1960s and 1970s, resulting in 661 PCCs of variable quality [90]. The American Association of Poison Control Centers (AAPCC) was established in 1958 primarily by pediatricians to develop public and professional education programs, promote cooperation between centers, and set standards for operation. In 1978, the AAPCC published strict standards for PCCs, and as a result the number of PCCs declined to 91 in 1995, 73 in 1998, and 55 in 2015 [20, 116]. These centers are staffed around the clock by nurses and pharmacists and usually are directed by pharmacists with some medical direction provided mostly by part-time medical toxicologists [99]. Some centers do not have adequate medical toxicologist availability, and most cases do not involve physician

consultation [81, 99]. PCCs have been shown to reduce unnecessary hospital visits and health care expenses, however, and serve as a resource for education, research, poison prevention efforts, and data collection [99, 100]. They also have been shown to be a reliable source of first aid and triage advice for the public and hospitals in cases of nonlife-threatening toxic exposures [84, 94]. Poison center services in the United States to physicians caring for poisoned patients have evolved over the years. Initially, PCCs were primarily consulted for ingredient information. The lack of availability of medical toxicologists at most hospitals has rendered PCCs as the default source of treatment recommendations. Most of this advice comes from nonphysicians working in PCCs, however. The need for medical toxicology resources for information on the treatment of critically poisoned patients is evident.

Likewise, in Europe the EAPCCT was formed in 1964 to share knowledge and to identify toxic hazards. There are now approximately 80 - European PCCs [53]. Networks of multiple centers operate in France, Germany, Italy, and the United Kingdom [53]. In the United States, poison centers can be contacted by the public and health care professionals at 1-800-222-1222, and in the United Kingdom the National Poisons Information Service is available to health care professionals and emergency departments at 0870-600-6266. Health officers, medical toxicologists, and pharmacists staff the centers, and they are often affiliated with poison treatment centers, ICUs, or emergency departments [53]. It has been advocated that these centers be part of a larger toxicology center that includes an analytic laboratory, inpatient treatment center, outpatient services, adverse drug reaction and occupational exposure advice, research, an expanded medical staff, and training [114, 118].

In addition to the United States and Europe, there are poison information centers operating on every continent worldwide except Antarctica. Many of these centers are still in the early stages of development. The Japan Poison Information Center was established in 1986 to serve a population of 124 million and received only about 35,000 calls in 1994 [119]. This represents a

case volume of only 27 per 100,000 population, in contrast to the United States's call volume of 920 calls per 100,000 at that time [119]. Before its dissolution, the World Federation of Associations of Poison Centers and Clinical Toxicologists issued a directory (Yellowtox) of worldwide poison information centers and analytic toxicology services, which still can be found at www.intox.org/pagesource/yellowtox/yellowtoxhtm.

Poison Treatment Centers

Poison treatment centers are highly specialized inpatient units directed by medical toxicologists and are capable of caring for the most complex cases of poisonings. Strong centralized regional poison treatment centers have flourished in some countries and serve as specialty care centers and institutes for toxicologic research, treatment advances, and education. Their origin probably is based in Scotland, where a "delirium ward" was established at the Royal Infirmary of Edinburgh in 1879 (Fig. 7) [30]. This unit gradually evolved into the Regional Poisoning Treatment Centre of Edinburgh, and by 1964 it cared for more than 90% of overdose patients in the Edinburgh area [30]. Another formal treatment center in Europe was founded in 1949 in Copenhagen, followed by other centers in Paris and in Romford, Essex, in the late 1950s [9, 30, 31]. The impetus for further development of centers in the United Kingdom in Birmingham, Dublin, Belfast, Cardiff, and London was the Atkins Report of 1962 and the Hill Report of 1968, in which the United Kingdom Ministry of Health recommended the establishment of regional poisoning treatment centers with consultants in toxicology and associated psychiatric and chemical toxicology laboratory services [31]. Other such centers were developed in Europe and Russia in the 1960s and more recently in the United States and Australia [48, 70, 115, 120].

In 1993, the AACT published standards for toxicology treatment centers [121]. Subsequently the ACMT refined and promoted those standards [115]. The Center for Poison Treatment Facility Assessment Guidelines can be found at www.acmt.net. The rationale for the existence of these

treatment centers is cited as the need for a dedicated professional staff to develop expertise, to assess and manage more efficiently medical and psychiatric issues, to advance knowledge rapidly by concentrating patients at dedicated sites for education and research, to focus psychosocial support for the patients' special needs, and to make it efficient to provide analytic laboratory support on-site [30, 31, 48, 114]. These guidelines recommend a medical staff of physicians board-certified in medical toxicology and nurses with toxicology specialty training, adequate beds consistently available for the care of the poisoned patient, quality improvement and teaching programs, and other physician specialists and equipment typically found in university hospitals or regional medical centers. Further details can be found in these guidelines on the ACMT website. There is no mechanism currently to certify centers meeting these standards, but it is known that there are at least 54 medical toxicology services in the USA, most of which would meet these standards [43].

These centers have been found to improve care of the toxicology patient. It was reported that in the first year of operation, the Copenhagen center reduced poisoning mortality by half by centralizing care [30]. The average LOS also has been reported to decrease, compared with general ICU or hospital ward admissions. In Australia, there was a reduction of 2–3 days in hospital stays for complicated poisoning cases at two toxicology centers, but there was not a statistical reduction in mortality [48, 122]. Use of health care resources also has been shown to decrease at these centers without compromising patient care, and the coupling of a treatment center with an aviation medicine service allows for efficient access to therapies unavailable in rural regions [123, 124]. Transfer of such seriously ill patients to specialty centers is supported in a policy statement of the ACEP, which states, "Patients should be transferred to a health care facility that meets their needs." [111] Transfer is often necessary to provide access to experienced medical toxicologists, antidotes, and analytic laboratory services not available elsewhere.

Regional poison treatment centers care for a highly variable number of patients annually.

Fig. 7 Royal Infirmary of Edinburgh 1879

Admissions to the Edinburgh center peaked at about 2,200 admissions per year, then declined to about 1,500 annual admissions in 1986 [9]. Two centers in Australia admitted 736 and 192 patients in years reported in the mid-1990s [48, 122]. The center in St. Petersburg, Russia, serves about 7 million people and reported more than 5,500 admissions per year [120].

In the United States, centers in Pennsylvania, Colorado, Arizona, and Utah each had about 500 annual admissions in 2002 [70]. The 54 centers participating in the ACMT ToxIC Registry, representing the busiest toxicology services in the country, treated an average of only 195 patients annually in 2014 [43]. Despite poisonings now causing more deaths than motor vehicle accidents, unlike the proliferation of trauma centers in every state, there has been little growth in medical toxicology specialty services [43, 68]. Even most university hospitals and large regional teaching centers have no toxicologists on their medical staff. This failure of modern medicine to meet this healthcare responsibility is due to a lack of recognition of the need for specialty toxicology care, the relatively low number of medical toxicologists due to a lack of adequately supported fellowship programs, and unfortunately less

opportunity to generate profit from these patients for the healthcare system [74]. Despite these barriers, medical toxicology has grown significantly in numbers of board-certified practitioners, peer-reviewed journals, fellowship programs, research, professional society size and activities, and bedside care by an increasing number of clinical sites. Likewise, critical care medicine has established its place as the designated physicians staffing ICUs, developing standardized evidence-based treatment protocols for improved patient care, and published research. The interaction between these two specialties should continue to grow and establish the standard of care for responding to the epidemic of drug overdoses and other critically ill toxicology patients.

A medical toxicologist must pay great attention to detail. Unlike other specialties, the toxicologist rarely has a gold-standard diagnostic test to confirm a poisoning or withdrawal condition. Instead, the medical toxicology evaluation requires a thorough history and physical examination and strategically ordered diagnostic testing. Then once all available information is gathered, the medical toxicologist must astutely interpret the findings within the appropriate clinical context. Therefore, the toxicologist can be nothing short of an astute diagnostician.

A key component of medical toxicology is separating the poisoned patient from alternative diagnoses. The Venn diagram of diagnoses for metabolic syndromes, traumatic injuries, infectious diseases, neurologic conditions, cardiac disease, pulmonary disorders, and toxicological illness has much overlap. Therefore, the diagnostic process in medical toxicology must rely heavily upon a detailed history, an astute physical examination, and contextually placed diagnostic testing in order to make the correct diagnosis.

Furthermore, the medical toxicologist must be prepared to exclude nontoxicological diagnoses. When the history is vague, the examination is equivocal, and the diagnostic tests are confusing, the medical toxicologist must have an open mind for alternative diagnoses. We have treated many patients who first present as an “overdose” but are later diagnosed with an ischemic stroke, encephalitis, or other medical condition. Certainly, we have witnessed the opposite scenario as well. Therefore,

This chapter is an update of the chapter on this topic written by Alex T. Proudfoot and J. Ward Donovan in the first edition of this text.

constant review and re-review of a clinical picture are paramount to ensure all findings remain consistent with any suspected diagnosis.

History

A detailed history is the most important first step in the diagnostic process in medical toxicology. Therefore, it is critical to gather data from all possible sources. Often, family, friends, and first responders offer great diagnostic clues. Electronic media is a potentially great source of information, including text messages, emails, and social media posts. Electronic media is particularly valuable since it is time-stamped.

When gathering history, where and under what circumstances the patient was found is critically important. Since first responders are trained to “size-up” a scene, they tend to provide the best history. Family and friends may only recognize crucial details when a scene is evaluated on the second attempt after coaching from the medical team. When obtaining history, crucial questions may include:

- Where was the patient found?
- When was the patient last seen in their normal state of health?
- What were the circumstances surrounding the patient’s discovery?
- Were any pill bottles, empty wrappers, or chemicals closely available?
- Are any suicide notes, text messages, or social media posts available?
- Is there any history of past drug overdoses, other attempts at self-harm, or substance abuse/withdrawal?

All these questions, and certainly many more, help identify the substances involved with a poisoning. Moreover, the history assists in identifying those at risk for aspiration pneumonia, rhabdomyolysis, compartment syndrome, or concomitant traumatic injuries.

A careful evaluation of available pills is extremely important. When pill bottles are identified, have family, friends, and first responders

bring the bottles to the hospital. This will assist in clearly identifying any substances. However, counting pills and attempting to correlate how many are missing is often a fruitless endeavor. Patients may hoard or sell pills and fail to take them as prescribed. Pill counts, therefore, are often unreliable. The mere availability of a particular substance suggests it may have been ingested. When pill bottles are not identified, prescriptions or substances available in the home can provide helpful clues. Patients will often ingest what is most easily available. When obtaining the medication history, it is important to inquire about prescriptions, over-the-counter medications, supplements, herbal preparations, and illicit drugs.

One point of caution is reliability of the obtained history. Patients, family, and friends are easily confused by drug names. For example, patients may be confused when attempting to identify over-the-counter pain relievers, such as ibuprofen and acetaminophen. Therefore, obtaining the exact pill bottles from the scene is the most reliable way to obtain this portion of the history.

Equally important is identification of chemical containers. When a chemical is identified in a possible exposure, obtaining the container from the scene is as important as obtaining specific pill bottles. The only reliable means to identify a substance is a well-labeled container. Using a witness’ recall as a means to identify a substance may be helpful in narrowing down the potential chemicals. However, specific chemical products have extreme variability in chemical composition even within the same brand. Therefore, errors in chemical identification are more likely when containers are not obtained.

The history is often the only means to identify a poison as few hospitals have the ability to promptly test all exogenous substances in serum or urine. Most hospitals can quickly obtain serum ethanol, salicylate, and acetaminophen concentrations. Yet, obtaining timely quantification of drugs and chemicals in body fluids remains elusive for most other exposures. Therefore, obtaining a detailed history, where possible, is a critically important element of the diagnostic process when dealing with poisoned patients.

Physical Examination

In conjunction with the history, the examination can confirm or refute the suspected toxicological diagnosis. In the absence of any available history, the examination may be the only initial clue in formulating a differential diagnosis. Furthermore, there is no substitute for a thorough bedside evaluation by a medical toxicologist. Medical toxicologists tend to astutely recognize unique signs of specific chemical intoxications or toxidromes.

Certainly, the examination must be tailored to the particular circumstances and clinical picture. This section is not designed to be all-inclusive. However, we merely highlight clinical signs that are high yield in evaluating the poisoned patient.

Vital Signs

Vital signs are vital! They offer the first picture into a patient's illness severity and determine what immediate actions should occur. In addition, serial vital sign measurements provide valuable information concerning a patient's changing clinical condition or response to treatment. Therefore, vital signs should be monitored closely and frequently.

Since many toxicants, drugs, and withdrawal states affect heart rate, the pulse is extremely important. Even a normal heart rate can suggest specific clinical conditions. In some cases, the heart rate is reflexively altered in a poisoning. For example, a toxicant exposure that results in hyper- or hypotension may result in reflexive brady- or tachycardia, respectively.

Blood pressure is also of utmost importance, and like heart rate, many toxicological diagnoses affect blood pressure. Yet more important than the actual blood pressure is the body's ability to adequately perfuse vital organs. When blood pressure measurements suggest the potential for inadequate perfusion (e.g., mean blood pressures ≤ 65 mmHg), we evaluate perfusion by alternative means. In these circumstances, we have borrowed knowledge gained in the treatment of sepsis. Along with the blood pressure, we will often use

serum lactate concentrations and mixed venous oxygen saturations [1]. This topic is discussed in greater detail in ► [Chap. 14, "The Assessment and Management of Hypotension and Shock in the Poisoned Patient."](#)

Respirations are effected by the patient's acid-base status or drugs/toxicants directly. However, merely looking at respiratory rate is often insufficient. One must astutely assess the depth of respirations as well as the rate of breathing. Many toxicants, drugs, and metabolic conditions may alter the minute ventilation without affecting the respiratory rate. In other words, the respiratory rate may remain normal while the patient is experiencing hyperpnea or hypopnea. These changes in minute ventilation are often revealed during a careful physical examination.

Body temperature measurements are often forgotten in the initial evaluation of the poison patient. Yet, the body temperature evaluation may be critically important. Alterations in body temperature can suggest a specific drug ingestion, chemical exposure, or withdrawal condition. For example, electron transport uncouplers, like salicylate, may cause hyperthermia. In other circumstances, the body temperature is merely a marker of the patient's environmental exposure. If a patient has an altered mental status after a poisoning, the patient is at the mercy of the environment. If left exposed to extreme temperatures, patients often present with hypo- or hyperthermia not from the toxicity, but merely from inability to seek shelter. Therefore, body temperature measurements need careful interpretation.

However, an elevated temperature is most strongly associated with mortality in sympathomimetic poisoning [2]. Therefore, body temperature measurements should not go unnoticed. Moreover, when extremes in body temperature are identified, efforts should be made to make the patient eutermic. Certainly, hyperthermia is a more immediate threat to life than hypothermia. Yet, hypothermia may lead to slower or unpredictable drug metabolism. Therefore, extremely high or low body temperatures are a concern and may offer diagnostic clues in the poisoned patient.

Clinical Signs

There are a number of clinical signs unique to the poisoned patient. One of the first signs encountered in the poisoned patient is odors. Odors are the result of malodorous chemicals, drugs, and drug metabolites. An obvious example is the detection of an ethanol odor, which may assist in identifying an intoxicated patient (See Table 1).

A thorough visual inspection of the patient's skin may be informative. This inspection should include a review of the skin color, dryness, and signs of traumatic injury. The actual poison may affect skin color as seen in the yellow staining after dinitrophenol poisoning. In other cases, the drug may cause a physiologic change resulting in skin coloration as in the flushed reddened appearance from antimuscarinic drugs. Cyanosis to a medical toxicologist does not merely suggest hypoxia but may also indicate methemoglobinemia or sulfhemoglobinemia. Some exposures lead to excessive histamine release, and patients may present with erythroderma such as with scombroid poisoning or the anaphylactoid reactions associated with vancomycin. Skin dryness may help differentiate between toxic syndromes. An old adage in medical toxicology is the toxicologist's handshake, which includes placing the clinician's hand in the armpit. Since antimuscarinic toxicity can result in facial diaphoresis, a dry armpit will more clearly differentiate antimuscarinic from sympathomimetic toxicity. Signs of skin trauma can provide contextual history about a patient.

Bruising may suggest concomitant traumatic injuries or the presence of a coagulopathy from liver disease or anticoagulant toxicity. Needle marks also tell much about a patient's social history. Skin necrosis or skin necrosis blisters are helpful diagnostic clues. Skin necrosis lesions are erythematous patches of various shapes that develop after prolonged immobility. One can often recreate the exact positioning of the patient by a careful evaluation of these skin lesions. With more prolonged contact, blisters may develop. These blisters have been called pressure necrosis blisters or even "barb blisters" since they were first noted in the era of barbiturate-associated overdoses. Nonetheless, skin necrosis and skin necrosis blisters inform the clinician that the patient suffered prolonged immobility and is at risk for aspiration pneumonia, skin breakdown, rhabdomyolysis, and compartment syndrome. Therefore, a simple inspection of the skin can provide much information about a patient.

A neurologic examination is of high clinical yield in the poisoned, or potentially poisoned, patient. This includes detection of any focal deficits, level of consciousness, speech, pupil size, muscle tone, and deep tendon reflexes. The importance of a detailed neurologic examination not only helps identify the correct toxicological diagnosis but can often identify alternative diagnoses, such as an ischemic stroke. Identification of any focal deficits should suggest the evaluation for nontoxicological diagnoses.

A patient's level of consciousness may suggest how much and, possibly, what type of poisoning is

Table 1 Odors of drugs and toxicants

Odor	Toxicant	Odor	Toxicant
Acetone	Alcoholic ketoacidosis	Mothballs	Camphor
	Isopropyl alcohol		Naphthalene
Acrid (pearlike)	Paraldehyde	Solvent/glue	Paradichlorobenzene
	Chloral hydrate		Toluene
Bitter almonds	Cyanide		Xylene
Disinfectant	Phenol		Trichloroethane
Garlic	Arsenical insecticides	Smoke	Tetrachloroethylene
	Organophosphate insecticides		Carbon monoxide
	Selenium		Cyanide
	Thallium		Clomethiazole
	Phosphorus	Wintergreen	Methyl salicylate
		Rotten eggs	Hydrogen sulfide

present. In clinical practice, the terms alert, lethargic, obtunded, stupor, and coma are helpful in describing a patients' mental status. Alert patients are awake and conversant. Lethargic patients require a loud verbal command for arousal. Obtundation requires shaking a patient as if awakening from sleep. Stupor requires a painful stimulus for arousal. Finally, a comatose patient is completely unarousable to multiple painful stimuli. Often the first step in a neurological examination, level of consciousness, also quickly determines who may need a more urgent intervention. This topic is discussed in greater detail in ► Chap. 19, "Toxicant-Induced Alterations in Consciousness."

The character of speech is quite telling. Fluency, articulation, and the ability to have an attentive conversation are important factors to review. For example, antimuscarinic patients have a characteristic mumbled and difficult to comprehend speech which, once recognized, helps identify this toxic syndrome. As medical toxicologists, we are often consulted for delirium. One characteristic finding of delirium is the inability to remain attentive. A conversation with a patient filled with distraction can suggest delirium. Therefore, the speech character and the conversation quality assist in the toxicological evaluation of potentially delirious patients.

Pupil size is one of the most commonly utilized neurologic examination findings for toxic patients. Most clinicians examine pupils to assess miosis in case of opioid toxicity. However, large pupils can suggest antimuscarinic or sympathomimetic toxicity. Yet, as a point of caution, the pupillary evaluation can be extremely misleading. For example, meperidine, an opioid, often presents with mid-sized pupils due to competing mechanisms from muscarinic antagonism and opioid agonism [3]. Therefore, interpret the pupil exam with much caution, but when utilized correctly, can provide a wealth of information.

The medical toxicologist must distinctly differentiate neuroleptic malignant syndrome (NMS) from serotonin syndrome. Muscle tone and reflexes are an important part of the neurologic examination. Except for the neurologist, most other specialists fail to include this as part of their

standard examination. Since the defining features of many toxic syndromes require an evaluation of tone and reflexes, these should become a routine part of the medical toxicologist's evaluation. The details of differentiating these two syndromes are found in ► Chaps. 31, "Neuroleptic Malignant Syndrome" and ► 24, "Serotonin Syndrome."

Toxidromes

After exposure to an unknown poison, any single sign, symptom, or laboratory abnormality will rarely permit the medical toxicologist to reach a definitive diagnosis. Rather, pattern recognition, the presence or absence of physical examination findings, and detailed historical evidence, together, will lead to speedy and accurate diagnoses.

In 1974, Mofenson and Greensher coined the term "toxidrome" to describe constellations of signs and symptoms that consistently result from particular classes of toxicants [4]. In clinical practice, however, it is more common to encounter partial toxidromes or mixed toxidromes. For example, toxicity from diphenhydramine, a first-generation antihistamine, often results in profound antimuscarinic findings. However, it is also sedating (due to antihistamine effects) and may not result in significant mydriasis due to both the antimuscarinic properties and alpha-adrenergic antagonism. Furthermore, diphenhydramine is a sodium channel antagonist and can cause QRS and QT prolongation and ventricular dysrhythmias, which are not typically caused by purely antimuscarinic agents such as the plant-derived alkaloids in belladonna. Moreover, many intentional drug overdoses involve more than one agent. Thus, patients commonly present with mixed findings. At times, the toxicities of each agent have additive effects as seen in the coingestion of a benzodiazepine and an opioid. In other cases, an agent may mask findings expected of another. As an example, the sympatholytic effects of clonidine may blunt the expected tachycardia and CNS excitation expected after a significant bupropion overdose [5]. Nevertheless, knowledge of the classic toxidromes provides a sound framework around which to

initiate appropriate evaluation, stabilization, and treatment of the critically poisoned patient. Table 2 provides a summary of the classic toxidromes.

Opioid Toxidrome

The toxidrome associated with opiate or opioid intoxication includes the classic triad of coma, miotic pupils, and respiratory depression. Depending on severity of illness, the clinician may also note modest bradycardia and/or hypotension. This toxidrome is not pathognomonic for opioid toxicity, and a similar presentation may suggest an α_2 -adrenergic agonist (e.g., clonidine, guanfacine, and tizanidine) toxicity, barbiturate toxicity, intracranial hemorrhage, and brain stem stroke.

In the proper historical setting, the triad of coma, miosis, and respiratory depression often prompts the use of naloxone. Naloxone has anecdotally been reported to reverse some cases of clonidine toxicity and yet should have no effect in the setting of intracranial hemorrhage, stroke, or barbiturate toxicity. Thus, naloxone is both diagnostic and therapeutic.

Opioid toxicity is discussed in greater detail in ► Chap. 62, “Opioids.”

Sedative-Hypnotic

A wide variety of pharmaceuticals characterize this toxidrome and generally stimulate central nervous system GABA-A chloride channels. Among the most commonly prescribed agents associated with the sedative-hypnotic toxidrome are benzodiazepines. Others such as ethanol, barbiturates, gabapentin, pregabalin, and zolpidem present with similar findings. Typically, the toxidrome is best described as “coma with preserved vital signs.” Though many sedative-hypnotic agents reduce blood pressure, heart rate, and body temperature, the reductions are often mild to modest depending on the severity of the ingestion or the specific drug involved. For example, barbiturate toxicity is more likely to cause significant respiratory depression, hypotension, and hypothermia

than other sedative-hypnotic agents. In general, patients appear deeply sedate and pupils are generally mid-sized, although they may be disconjugate. Contrary to popular belief, patients generally do not exhibit respiratory depression in the setting of isolated oral benzodiazepine ingestions [6]. Hypoxia with respiratory depression more commonly develops after intravenous administration or secondarily from upper airway obstruction in the setting of obesity or impaired chest wall excursion. Overall, the sedative-hypnotic toxidrome is the hardest to characterize due to the wide variety of drugs involved and the nonspecific presentation.

Toxicity from these agents is discussed in great detail in ► Chap. 45, “Anxiolytics, Sedatives, and Hypnotics.”

Antimuscarinic Toxidrome

The antimuscarinic toxidrome, also referred to as the anticholinergic syndrome, in full or in part, is commonly evident in intentional drug overdoses or adverse drug reactions owing the ubiquitous nature of xenobiotics that affect muscarinic neurotransmission. Examples of drug classes that frequently exhibit antimuscarinic properties include first-generation antihistamines, antipsychotics, and class 1A antidysrhythmics. Additionally, alkaloids (atropine, scopolamine, and hyoscyamine) derived from many plants in the Solanaceae family – e.g., Jimson Weed (*Datura stramonium*), Angel’s Trumpet (*Brugmansia sp.*), Deadly Nightshade (*Atropa belladonna*) – are abused by teens and used in religious ceremonies throughout the Americas.

The effects of antimuscarinic drugs are indicative of competitive antagonism of muscarinic acetylcholine receptors [7]. The constellation of tachycardia, mild hypertension, mild hyperthermia, skin flushing, xerostomia and anhidrosis, mydriasis, urinary retention, delirium, carphologia (picking behavior), and muffled or garbled speech suggests antimuscarinic poisoning. Patients will commonly experience visual or tactile hallucinations too. In clinical practice, rarely do patients present with all these signs as

Table 2 Summary of the classic toxidromes

	Heart rate	Blood pressure	Respirations	Temperature	Pupils	Skin	CNS	Distinctive feature(s)
Opioid	↓	↓	↓↓	↓	Miosis	No change	↓ LOC	Coma, miosis, hypoventilation
Sedative-hypnotic	↓	↓	↓	↓	No change	No change	↓ LOC	Coma with normal vitals
Antimuscarinic	↑↑	↑	↑	↑	Mydriasis	Anhidrosis (except face)	Agitated delirium	Carphologia, mumbling speech
Cholinergic	↓↓	↓↓	↑	No change	Miosis	Diaphoretic	↓ LOC, seizures	Bradycardia, bronchorrhea, bronchospasm
Sympathomimetic	↑↑	↑↑	↑	↑	Mydriasis	Diaphoretic	Agitated delirium, seizures	Mydriasis, agitation, tachycardia, hypertension
Serotonin syndrome	↑↑	↑	↑	↑	Mydriasis	Mild diaphoresis	Agitated delirium, seizures	Lower extremity hyperreflexia
Neuroleptic malignant syndrome	↑	↑↑	↑	↑↑	Varies	Varies	Varies – agitated delirium to coma	Cogwheel rigidity with hyporeflexia

many agents that precipitate antimuscarinic findings have other competing pharmacologic effects. For example, antipsychotics exhibit varying degrees of α 1-adrenergic antagonism and thus may cause vasodilatory hypotension and pupillary miosis in the context of an otherwise antimuscarinic-appearing patient. The antimuscarinic syndrome is discussed in greater detail in ► [Chap. 23, “Anticholinergic Syndrome.”](#)

The antidote for antimuscarinic toxicity is physostigmine – a reversible acetylcholinesterase inhibitor that crosses the blood brain barrier. Physostigmine is both a diagnostic and therapeutic tool, but caution should be undertaken owing to the rare risk of precipitating self-limited cholinergic effects including seizures. In doses of 1–2 mg administered at 1 mg/min, physostigmine should reverse antimuscarinic signs. Physostigmine is especially useful when the antimuscarinic diagnosis may prevent a costly and invasive workup such as computerized tomographic (CT) or magnetic resonance imaging of the brain or lumbar punctures. More information on the clinical pharmacology and use of physostigmine is available in ► [Chap. 161, “Physostigmine.”](#)

Cholinergic Syndrome

The cholinergic toxidrome is seen less frequently in the USA or Western Europe than in other parts of the world due to regulation and limited availability of organophosphate pesticides. However, the increased popularity of electronic cigarettes has resulted in a rise of cholinergic toxicity due to the availability of concentrated liquid nicotine [8]. Furthermore, some chemical weapons, namely nerve agents, are highly potent cholinergic toxicants. Thus, rapid recognition of this syndrome is critical for prehospital, emergency medicine, and critical care providers. The classic cholinergic toxidrome includes diarrhea, urinary incontinence, miosis, salivation, vomiting, diaphoresis, and, most critically, bronchorrhea, bronchospasm, and bradycardia. These symptoms often present in conjunction with neuromuscular fasciculations, which may lead to skeletal muscle paralysis and respiratory

insufficiency. Seizures are also common due to elevated cerebral acetylcholine levels [9]. Additional information is available in ► [Chaps. 92, “Organophosphate and Carbamate Insecticide”](#) and ► [135, “Nerve Agents.”](#)

Some cholinergic toxicants are direct muscarinic acetylcholine receptor agonists and present with classic muscarinic findings described above. Notably, *Clitocybe* sp. and *Inocybe* sp. mushrooms contain significant concentrations of muscarine, a direct muscarinic receptor agonist. Other agents exert cholinergic effects by direct agonism of either nicotinic or muscarinic acetylcholine receptors. In particular, nicotinic agonists paradoxically lead to a constellation of cholinergic and sympathomimetic findings since nicotinic receptors are located on postganglionic nerves in both the sympathetic and parasympathetic nervous systems. In turn, nicotine often demonstrates a predominance of sympathomimetic findings early and parasympathetic findings later. Nicotine toxicity in toddlers classically starts with gastrointestinal distress, tachycardia, hypertension, agitated delirium and seizures followed by hypotension, bradycardia, and neuromuscular paralysis [10]. Therefore, some cholinergic toxicants may present with a constellation of findings that appear inconsistent with the ‘classic’ cholinergic toxidrome.

Sympathomimetic Toxidrome

Clinically, the sympathomimetic toxidrome is difficult to differentiate from antimuscarinic poisoning or alcohol withdrawal. There is a wide array of poisonings that result in sympathomimesis; however, the unifying characteristic is inappropriate adrenergic tone. Cocaine, amphetamines (including cathinone derivatives), and methylxanthines all produce findings of sympathomimetic toxicity. The toxicity is exemplified by tachycardia, hypertension, diaphoresis, mydriasis, and hyperthermia. Patients may have preserved mental status; however, in severe cases, agitated delirium and seizures may develop. In cases of hyperactivity or agitation, hyperthermia may result from excess skeletal muscle activity or altered serotonin and dopamine neurotransmission [11]. Further

details regarding this syndrome is available in ► [Chap. 25, “Sympathomimetic Syndrome.”](#)

Serotonin Syndrome

The constellation of autonomic instability (typically manifest as tachycardia and mild hypertension), altered mental status, and rigidity – particularly involving the lower extremities – is suggestive of serotonin syndrome. Normally, reflexes are diminished in rigidity; however, the sine quae non of serotonin syndrome is hyperreflexia despite rigidity. This toxidrome exists on a spectrum. Mild findings present with tachycardia and lower extremity hyperreflexia, while severe disease includes hyperthermia and hypertonic rigidity. Serotonin syndrome can occur in the setting of therapeutic use of serotonergic drugs such as selective serotonin reuptake inhibitors, serotonin/norepinephrine reuptake inhibitors, and tricyclic antidepressants [12]. Unlike the oft-confused neuroleptic malignant syndrome, serotonin syndrome develops abruptly over hours and resolves quickly over the course of 24–48 h in most scenarios. Neuroleptic malignant syndrome does not present with hyperreflexia. See ► [Chap. 24, “Serotonin Syndrome”](#) for further details.

Neuroleptic Malignant Syndrome

The sine quae non of the neuroleptic malignant syndrome is skeletal muscle rigidity and hyporeflexia in the context of antipsychotic use or dopaminergic withdrawal. In the absence of antipsychotic use or dopaminergic drug withdrawal, the diagnosis is not NMS. Classically, NMS begins insidiously and worsens over the course of days. The same triad as serotonin syndrome (autonomic instability, altered mental status, and rigidity) exemplifies the syndrome; however, diminished reflexes chiefly differentiate it from serotonin syndrome. See ► [Chap. 31, “Neuroleptic Malignant Syndrome”](#) for further details.

Technically, every xenobiotic has its own specific toxidrome. For example, salicylate-

poisoning presents with tachycardia, nausea and vomiting, diaphoresis, a high-anion gap metabolic acidosis, and respiratory alkalosis, while iron toxicity presents with severe GI distress, shock, leukocytosis, and lactate-associated metabolic acidosis followed by acute liver injury. In later chapters, the reader will appreciate nuances of varying presentations for each specific poison that will aid in expeditious diagnoses allowing providers to render timely and appropriate treatment.

Diagnostic Testing

As a rule, ancillary testing of poisoned patients is often directed by the history and physical examination. However, some tests are particularly valuable when evaluating the critically ill poisoned patient. This is especially important when attempting to determine the severity of illness. This section is not intended to be all-inclusive but merely a framework to provide context for the use of these diagnostic modalities as described in other sections of this book.

EKG

A 12-lead EKG and continuous cardiac monitoring are important tools in the initial diagnostic workup of the poisoned patient. This is particularly important because cardiac dysrhythmia is a common cause of death in the poisoned patient. Early identification of cardiac dysrhythmias and QRS or QT interval abnormalities is paramount and will dictate further treatment. A normal EKG can also suggest lack of significant exposure in certain cases, such as after tricyclic antidepressant overdose.

Poisonings often manifest changes in the EKG. Depending upon the exact exposure, the EKG may demonstrate tachycardia, bradycardia, ventricular dysrhythmias, QRS and/or QT prolongation, among others. Since the EKG is quickly obtained and often completed prior to other tests, the EKG is typically the first evaluation of a toxidrome. Hence, we discuss this diagnostic test first.

Most often, the medical toxicologist uses the EKG to evaluate intervals. Not only does QRS or QT prolongation suggest ingestion, the length of prolongation is often dose-related. This is particularly evident in tricyclic antidepressant overdose wherein the degree of QRS elongation is suggestive of more clinically significant ingestions and predictive of more severe pathology [13]. Serial EKGs (much like an EKG in the evaluation of an acute coronary syndrome) may help determine effectiveness of treatment and progression of poisoning. This strategy is most important for the tricyclic antidepressant overdose patient receiving IV sodium bicarbonate therapy for a prolonged QRS. Therefore, an EKG is a great diagnostic test during the initial evaluation of a poisoned patient and can help determine severity of illness. Please refer to ► [Chap. 21, “Cardiac Conduction and Rate Disturbances”](#) for a further discussion of this topic.

Arterial Blood Gases

Arterial blood gases (ABGs) add valuable information when evaluating the critically ill poisoned patient. Like an EKG, the ABG provides rapid results and can help determine the severity of the patient's illness in short order. The ABG provides a quick assessment of a patient's acid-base status (pH), oxygenation (PO_2), and ventilation (PCO_2). Since an ABG is quickly obtained, one can immediately use the information to correct an acid-base disturbance, oxygenation, and/or ventilation. Additionally, serial ABGs are a helpful resource when judging a patient's changing condition or response to treatment. Regardless of the type of exposure, an ABG is a helpful screening tool for an undifferentiated toxicology patient. Notably, however, measurement of the pH and PCO_2 are accurately assessed with a venous blood gas. Unless the P_aO_2 is specifically required, a venous blood gas is sufficient and preferable due to ease and decreased risk since there is no arterial puncture.

Characterization of any acid-base disturbance is often of value in diagnosing a particular

poisoning. The patient's acid-base status is then useful in guiding therapeutic interventions. An elevated anion gap metabolic acidosis is the most common acid-base disturbance seen in poisoned patients. Mnemonics used in formulating a differential diagnosis for an anion gap acidosis are riddled with a disproportionately large number of drugs or chemicals; ► [Chap. 15, “Acid–Base Balance in the Poisoned Patient”](#) this is discussed further elsewhere. Normal anion gap metabolic acidosis is less commonly identified in poisoned patients but is seen after exposure to carbonic anhydrase inhibitors and toluene.

When assessing the patient's respiratory status, the ABG will provide helpful information not relayed by pulse oximeters. Since many poisoned patients suffer from respiratory depression, the ABG will not only relay information regarding oxygenation, but also ventilation. Many poisoned patients present with altered mental status and adequate oxygenation but instead have hypercarbia discovered later.

Biochemical Analysis

In many poisoned patients, a complete blood count and electrolytes are reflexively ordered. Unless a particular toxicant is known to cause hematologic derangements such as hemolysis, the complete blood cell count is usually unhelpful. Nonspecific leukocytosis is common in overdose and likely due to demargination from acute stress reaction. We have seen white blood cell counts in excess of 40,000 cell/ μ L in sympathomimetic overdoses without concomitant infection. Acute anemia may provide evidence of an acute hemolytic process. Macrocytosis may suggest chronic ethanol use or acquired functional vitamin B12 deficiency from nitrous oxide abuse.

Electrolyte abnormalities, particularly those associated with acid-base disorders, are telling in the undifferentiated poisoned patient. The toxicological differential diagnosis for an anion gap metabolic acidosis is much broader than suggested by the frequently employed “MUDPILES” mnemonic. Certainly, high-anion

gap metabolic acidosis in the absence of hyperglycemia or shock is highly suggestive of a toxicological cause. Additionally, lactate elevation in the absence of shock, hepatic failure, sepsis, or abdominal catastrophes also suggests a toxicologic cause such as carbon monoxide, cyanide, or methanol poisoning.

Derangements in sodium homeostasis may suggest the syndrome of inappropriate antidiuretic hormone in the case of SSRI toxicity or diabetes insipidus in the case of lithium poisoning. Hyperchloremic nonanion gap acidosis may suggest topiramate toxicity. Profound hypokalemia occurs with barium, toluene, and methylxanthines. Therefore, the astute clinician can use electrolytes to evaluate exposures and compare to a known list of possible exposures.

Creatinine and blood urea nitrogen (BUN), as markers of renal function, are important in the evaluation of the critically poisoned patient. Many toxicants are renally eliminated, and the presence of renal failure may prompt initiation of extracorporeal removal in select cases. Furthermore, many toxicants, such as ethylene glycol, are themselves nephrotoxic, and thus a baseline evaluation and trending of renal function is crucial.

Elevations in aspartate and alanine transaminases occur in the setting of liver injury but also with rhabdomyolysis. One of the most common toxicological causes of acute liver injury is acetaminophen poisoning. In the undifferentiated patient, elevation of transaminases prompts consideration for empiric N-acetylcysteine treatment due to the prevalence of acetaminophen toxicity. Otherwise, there is a litany of hepatotoxins (including plants, essential oils, herbal supplements, over-the-counter and prescribed medications, some halogenated hydrocarbons, etc.), and only a careful history will allow the clinician to differentiate causes in the absence of other signs or symptoms. As important as transaminases may be for acetaminophen poisoning, the PT/INR is equally important. While transaminases provide evidence for hepatocyte injury, derangements in the PT/INR reflect hepatic synthetic dysfunction.

Toxicology Testing

Urine screens for drugs of abuse are rarely useful in the diagnosis or management of acutely poisoned patients. Most urine drug screens are enzyme-multiplied immunoassays and as such are limited by false-positive and false-negative results. On one hand, a patient who abuses fentanyl may present with the classic opioid toxidrome of coma, miosis, and respiratory depression, but their urine opiate screen could remain negative. On the other hand, a positive urinary result does not automatically suggest the patient is actually toxic from the detected substance. Since the bladder is a reservoir and urine drug testing often evaluates for the presence of metabolites, a positive urinary drug test does not provide confidence that a substance is the current cause of the patient's presentation. The clinical picture is most important. Any interpretation of urine drug testing must consider the context of a clinical examination and limitations of the test. We, therefore, place little weight on this test.

In direct opposition to urine drug testing, serum quantitative testing is particularly valuable. Quantitative measurements provide valuable information about the severity of exposure in real time. Routine serum measurement of salicylate, acetaminophen, and ethanol are encouraged since exposures are commonplace. Importantly, toxicity from any one of these drugs has a specific treatment. Many hospitals can also obtain serum concentrations of lithium and antiepileptics. If the patient has access to any of these drugs, serum quantitation may reveal the cause of the toxicity. We do not routinely encourage measuring drug levels if there is a delay in obtaining the results. This rarely offers real-time results and rarely affects patient care. However, if in-house testing is available for a specific drug in question, serum quantitation is frequently extremely helpful.

Osmolal Gap

Most hospitals are unable to obtain toxic alcohol (methanol, ethylene glycol, isopropanol)

Fig. 1 Calculation of the osmolality gap (where glucose, BUN, and ethanol reported in mg/dL)

$$2x [Na] + \frac{[Glucose]}{18} + \frac{[BUN]}{2.8} + \frac{[Etanol]}{4.6} = \text{Measured Osmolality}$$

$$\text{Osmolality Gap} = (\text{Measured Osmolality}) - (\text{Calculated Osmolality})$$

Fig. 2 Conversion of mg/dL to mmol/L

$$\frac{\text{mmol}}{L} = \frac{\left[\frac{\text{mg}}{\text{dL}} \right]}{\left[\frac{\text{gm}}{\text{mol}} \times \frac{1000 \text{ mg}}{\text{gm}} \times \frac{\text{mol}}{1000 \text{ mmol}} \right]} \times \frac{10 \text{ dL}}{L}$$

concentrations in clinically meaningful timeframes; thus, the clinical use of serum osmolality in an attempt to estimate toxic alcohol concentrations becomes an important discussion. Indications for obtaining a serum osmolality include historical information suggesting a toxic alcohol ingestion or an elevated gap metabolic acidosis of unknown etiology.

The osmol gap is the difference between measured osmolality and calculated osmolality (Fig. 1). Osmol gap elevations (typically >10 mosm/L) are generally considered abnormal. However, an osmolality gap ≥ 20 mosm/L exceeds 2 standard deviations of the population-based mean and represents a more clearly abnormal result. Therefore, interpreting gaps <20 mosm/L are less clear.

Calculation of the osmol gap requires simultaneous measurement of serum sodium, glucose, BUN, and ethanol concentrations, plus a serum osmolality. There are two general methods of osmolality calculation – boiling point elevation and freezing point depression. The latter is preferred because alcohols are volatile and may be lost in boiling point assessments. In the USA, unlike many other countries, calculation of the osmol gap requires conversion of glucose, BUN, and ethanol levels (all usually reported in mg/dL) to SI units (mmol/L) (Fig. 2). Once calculated, an osmol gap can also estimate a toxic alcohol concentration by multiplying the gap by one-tenth the molecular weight of the suspected toxic alcohol. For example, if the osmol gap is 100, the estimated serum ethylene glycol concentration is 621 mg/dL.

Patients with severe alcohol intoxication (e.g., levels in excess of 300 mg/dL [65 mmol/L]) typically have an elevation of osmol gap even when

one accounts for the serum ethanol concentration. The identity of the unmeasured osmols is unclear but likely the result of elevated lactate, acetaldehyde and/or acetate levels.

Imaging

Imaging for diagnostic purposes in poisoned patients is generally of limited value. Rare exceptions include ingestion of selected heavy metals, such as iron and lead. For example, the presence of iron tablets in the gastrointestinal tract on radiography may prompt initiation of whole bowel irrigation. In cases of body packing, a CT scan of the abdomen and pelvis may reveal the body burden of packaged drug, hollow visceral perforation, or obstruction. CT imaging of the chest, abdomen, and pelvis is becoming increasingly useful in predicting injury severity after caustic ingestion [14]. Occasionally, CT imaging of the head may reveal pathognomonic findings (e.g., bilateral basal ganglia infarction), suggestive of toxicity from an electron transport chain inhibitor (e.g., cyanide, methanol, carbon monoxide). However, in general, imaging provides useful information in limited cases.

Aggressive supportive care is the mainstay of treatment provided to patients in the intensive care unit (ICU). Basic aspects of care must be reevaluated or adjusted to account for unique aspects in the pathophysiology of the critically ill poisoned patient. This may include the use of gastrointestinal (GI) decontamination or the administration of antidotes. This chapter discusses the initial management and resuscitation of the critically ill poisoned patient. Subsequent chapters describe therapeutic decisions unique to particular drugs and xenobiotics and discuss specific antidotes in greater detail.

General Approach to Patient Data for the Poisoned Patient

The organization of data may be problem based (e.g., phenytoin overdose or hydrocarbon aspiration) or system based (i.e., pulmonary, cardiovascular, renal, or hematologic). The system-based approach, typically used for critical care patients, better organizes large quantities of data (e.g., liver failure following acetaminophen ingestion causing coagulopathy, increased intracranial pressure, and hepatopulmonary syndrome). For the toxicology patient, substance-specific problems and therapies should also be noted. The system-based approach prevents important therapeutic and organizational issues from being overlooked (Table 1). The system-based approach clearly identifies the number of organ system failures, a

Table 1 System-based approach to the poisoned intensive care unit patient

General
Vital signs: current HR, BP, RR, temperature
Avoid giving vital sign ranges (e.g., “systolic BP ranging from 50–180”), as this can be misleading and counterinformative
State vital signs that are “abnormal” (e.g., fever spikes, hypotension)
Input and outputs; weight
Cardiovascular
Cardiac biomarkers and ECG
Inotropes and vasopressors: dopamine, dobutamine, norepinephrine, epinephrine, phenylephrine, glucagon, high-dose insulin euglycemia
Advanced monitoring: CVP, PAP, PCWP, CO, SVR, SvO ₂ , stroke volume, IVC diameter and collapse, carotid velocity time integral
Echocardiogram, MRI, CT
Pulmonary
Ventilator settings
Mode and rate, V _T (tidal volume), PEEP, FiO ₂
Pressure support, if added to SIMV or CPAP modes
Report the patient’s actual RR, V _T , and V _E (minute volume)
Airway peak and plateau pressures, auto-PEEP
Arterial blood gases: pH, PCO ₂ , PO ₂ , SaO ₂
Liberation parameters: NIF (MIP), rapid shallow breathing index
Chest x-ray and CT findings
Gastrointestinal
Liver function tests, amylase and lipase, albumin
Abdominal ultrasound and CT findings
Bowel function/elimination
Renal
Electrolytes, BUN, creatinine, anion gap, osmolar gap
Infectious diseases
Maximum temperature (minimum temperature when low), antibiotics (day number), positive cultures, cultures outstanding
WBC and bands
Neurologic
Sedation and paralysis; analgesia
Electroencephalographic findings
Hematologic
Coagulation studies, platelet count, DIC information
Endocrine
Blood glucose
Corticosteroid levels and results of stimulation tests
ICU housekeeping
Stress ulcer and DVT prophylaxis
Nutritional support (tube feedings or TPN)

criterion used to determine the need for ICU admission and to predict ICU mortality [1].

Patients with Toxicologic Exposures Admitted to an Intensive Care Unit

The American Association of Poison Control Centers (AAPCC) National Poison Data System (NPDS) reported 101,141 exposure-related ICU admissions (3.5% of all toxicant exposures and 16.5% of all exposures managed in a health-care facility) in 2014 [2]. Of all the patients included in the NPDS, 7% had medical outcomes classified as “moderate” and 1% were classified as “major.” For patients 20 years of age or older, 15% had medical outcomes classified as “moderate” and 2% as “major.” Presumably patients with moderate or major effects were more likely to require admissions to the ICU. Moderate effect is defined by AAPCC as the patient exhibiting signs or symptoms as a result of the exposure that were more pronounced, more prolonged, or more

systemic in nature than minor symptoms. Examples include acid–base disturbances, high fever, disorientation, hypotension responsive to treatment, and isolated brief seizures. Major effect is defined by AAPCC as the patient exhibiting signs or symptoms that were life-threatening or resulted in significant residual disability or disfigurement. Examples include repeated seizures or status epilepticus, respiratory compromise requiring intubation, ventricular tachycardia, hypotension, cardiac or respiratory arrest, esophageal stricture, and disseminated intravascular coagulation. Patients experienced major effects for less than 24 h 29% of the time, between 24 h and 3 days 34% of the time, and between 3 days and 1 week 19% of the time. Since 2000, cases with more serious outcomes increased by 4.29% (95% CI 3.87–4.72%) per year. Some patients with less pronounced effects were also admitted to the ICU due to hospital requirements to admit all suicidal patients to the ICU in order for them to be closely monitored.

Initial Assessment

As with any unstable or critically ill patient, the ABCs (airway, breathing, circulation) of basic life support take priority (Level III recommendation). In the poisoned patient, therapeutic interventions and diagnostic evaluation often are initiated simultaneously (see ► [Chap. 2, “The Diagnostic Process in Medical Toxicology”](#)). Findings on physical examination often guide the initial therapy. Airway patency and ventilatory drive frequently are compromised in patients with decreased mental status and may need immediate intervention. The decision to administer certain antidotes such as thiamine, glucose, naloxone, flumazenil, and physostigmine is made early in the diagnostic stage, generally before the patient is admitted to the ICU. Although naloxone and flumazenil may obviate the need for intubation in selected patients, flumazenil should only be cautiously administered to patients who may have long-term benzodiazepine use or to patients who have co-ingested a benzodiazepine and drugs that lower the seizure threshold. The risk of a

flumazenil-induced seizure must be weighed against complications occurring during intubation (Level I recommendation). Further discussions of benzodiazepine poisoning and the use of flumazenil are found in ► [Chaps. 45, “Anxiolytics, Sedatives, and Hypnotics,”](#) and ► [148, “Flumazenil.”](#) For further discussion about the role of physostigmine, see ► [Chaps. 23, “Anticholinergic Syndrome,”](#) and ► [161, “Physostigmine”](#). Decisions regarding GI decontamination, if any, which may include administration of single-dose activated charcoal (AC) and whole bowel irrigation (WBI) are also made early in the patient’s course, likely before the patient arrives in the ICU. Currently, there is no role for gastric lavage. Diagnostic tests often need to be repeated to follow the ongoing effects of the toxicant (e.g., acid–base status in ethylene glycol ingestion) or to determine effectiveness of treatment (e.g., electrocardiogram after administration of sodium bicarbonate in patients with signs of sodium channel blockade, such as after overdose of tricyclic antidepressants [TCAs] or Type 1a or 1c antiarrhythmics, or trending of transaminases following toxic ingestions of acetaminophen [paracetamol]). Various types of toxicology laboratory screening or quantitative testing often are performed, and proper interpretation of the results is essential to making appropriate therapeutic decisions. Further information related to this aspect of the care of poisoned patients can be found in ► [Chap. 2, “The Diagnostic Process in Medical Toxicology.”](#) Although GI decontamination if used should be initiated in the emergency department, the decision to continue GI decontamination in the ICU is usually toxicant specific and discussed later in this chapter.

Supportive Care Decisions

Airway Maintenance

The loss of airway-protective reflexes and concern for aspiration or the presence of respiratory failure dictates the need to secure the airway. Securing the airway should be accomplished by tracheal intubation as noninvasive ventilation is relatively

contraindicated in patients with hemodynamic instability, patients with inability to protect their airway, and patients with a full stomach (including pregnancy and obesity) [3]. Orotracheal intubation, if possible, is preferred over nasotracheal intubation for many reasons. Nasotracheal intubation causes a statistically significant increase in sinusitis [4–7], purulent and serous otitis [8], ventilator-associated pneumonia [9], and sepsis [10] and is technically more difficult compared with orotracheal intubation. Typically only a 6.0- or 6.5-mm endotracheal tube is used for nasotracheal intubation. These narrow tubes have increased airflow resistance compared with the larger diameter tubes used for orotracheal intubation. Airflow resistance increases after several days of intubation as secretions harden inside the tube and decrease the tube's diameter [11]. Increased airflow resistance can increase respiratory workload significantly. Should bronchoscopy be required (e.g., new infiltrates on chest x-ray, mucus plugging, lung collapse), the narrower, longer nasotracheal tube makes it more difficult, if not impossible, to pass a flexible bronchoscope.

An exception may be in patients with significant caustic injuries and swelling where nasotracheal intubation may be more practical than orotracheal intubation. In addition in patients with anticipated difficult airways, either nasotracheal intubation or an “awake orotracheal intubation” should be considered (Level III recommendation). Ingestion of caustic agents, with concomitant injury to the respiratory tract and oropharynx, requires special consideration in airway maintenance. Although airway obstruction is rare in patients who ingest caustic agents [12], airway patency is more at risk with the ingestion of solid rather than liquid caustic agents [13]. Only 11 of 33 children (33%) with either acid or alkali ingestions required intubation [14]. Seven children required immediate intubation for respiratory distress or airway obstruction, and the other four had minimal or no respiratory symptoms but were intubated after endoscopic findings of supraglottic edema. Most intubations after caustic ingestion can be done under direct visualization using standard direct laryngoscopic

techniques. The equipment for alternative methods of securing the airway (e.g., cricothyrotomy) should be in place before any paralytic or induction agent is given, however, in case the normal visual landmarks are obscured and orotracheal intubation cannot be accomplished. In the 11 intubated pediatric patients described above, no adverse consequences occurred as a result of orotracheal intubation [14].

Most patients are successfully intubated using a rapid sequence intubation (RSI) strategy which includes a period of preoxygenation. Preoxygenation prior to intubation assists in avoiding hypoxemia during the apneic period of RSI and decreases peri-intubation morbidity and mortality [15] (Level II-3 recommendation). However either due to an inability to adequately preoxygenate the patient or concerns that the patient may be difficult to intubate, strategies aside from RSI should be considered (Level III recommendation). While these strategies are well described, they have not been studied in the poisoned patient.

Delayed sequence intubation (DSI) temporarily separates the administration of the induction agent from the muscle relaxant in order to allow adequate preintubation preparation and preoxygenation [16, 17]. In DSI, patients are sedated with ketamine which causes dissociation and sedation while allowing for adequate preoxygenation before the administration of a muscle relaxant. This strategy is particularly useful in the delirious or agitated patient that cannot otherwise be preoxygenated. In one observational study, patients were induced with ketamine (starting dose of 1 mg/kg titrated to adequate sedation) and then preoxygenated for 3 min with either a non-rebreather or positive pressure ventilation (NIPPV) prior to the administration of a muscle relaxant [16]. Saturations increased from 89.9% prior to DSI to 98.8% afterward with an average increase of 8.9% (95% CI 6.4–10.9%). There were no complications and all patients were successfully intubated, aside from two patients that significantly improved and no longer required intubation.

Another potential strategy is an “awake intubation,” where the patient is given a light sedative

such as ketamine but is mainly anesthetized with local anesthetics prior to intubation [18, 19]. An awake intubation can be attempted via direct visualization or with the assistance of a fiberoptic scope. This intubation strategy can be considered in patients requiring urgent intubation, but that may have a contraindication to receiving a sedative and muscle relaxant that impairs their ability to breathe. Patients with caustic injuries requiring intubation due to concerns of airway deterioration may be candidates for an awake intubation (Level III recommendation).

Apneic oxygenation is used to extend the safe apnea period beyond the time which can be achieved with preoxygenation and should be considered regardless of the method of intubation [17, 20] (Level II-3 recommendation). Even without respiratory effort, the pharynx can be filled with oxygen using a high-flow nasal cannula and acts as a reservoir [21]. During intubation, the aveoli will continue to take up oxygen that then diffuses into the bloodstream and prevents hypoxia. Patients were preoxygenated, paralyzed, intubated, and placed on a ventilator in one study [22]. They continued to be oxygenated at 1.0 FiO₂ but were not given any ventilation; no patients developed saturations less than 98% despite being paralyzed and not ventilated.

Respiratory Function

Adequacy of respiratory function must be assessed immediately after the airway is secured. The causes of respiratory failure can be divided into four groups (Table 2), as follows [23]:

1. Hypoxemic (type I) respiratory failure arises from the flooding or collapse of alveoli, resulting in intrapulmonary shunting. Patients are hypoxic but have a low or normal CO₂ concentration.
2. Hypercapnic (type II) respiratory failure is caused by inadequate alveolar ventilation from either decreased respiratory drive or an imbalance between respiratory load and respiratory muscle strength. Patients will have elevated CO₂ concentrations and may be hypoxic.

3. Postoperative (type III) respiratory failure is caused by pain leading to shallow breathing, atelectasis, hypoxemia, and narcotic administration to control pain, which further decreases respiratory drive and worsens atelectasis.
4. Shock-related (type IV) respiratory failure is caused by a combination of inadequate oxygen delivery to respiratory muscles and increased total-body metabolic demands.

Type I respiratory failure in the overdose patient typically is caused by aspiration or agents that cause the acute respiratory distress syndrome (ARDS) (e.g., salicylates). Type II respiratory failure can be caused by ingestion of drugs that decrease respiratory drive (e.g., narcotic or other sedative overdose) or cause respiratory muscle weakness (e.g., botulism). Type IV respiratory failure can be associated with any drug ingestion that causes myocardial depression or shock, such as calcium channel antagonists. Type III respiratory failure is not applicable to the overdose patient. The type of respiratory failure may change during a patient's hospitalization. For instance, patients may initially present with type IV respiratory failure from cardiogenic shock. As the patient's hemodynamics improve, they may be difficult to wean from the ventilator due to the development of type II respiratory failure from the accumulation of sedatives and analgesics administered in the ICU.

The therapeutic approach to each type of respiratory failure is determined by the underlying pathophysiology. Type I respiratory failure is treated with a high fraction of inspired oxygen (FiO₂) and the judicious use of positive end-expiratory pressure (PEEP). Some focal lung lesions, such as lesions from hydrocarbon aspiration, may not be PEEP responsive, however. In these situations, high levels of PEEP (>10 cm H₂O) may worsen the patient's condition by decreasing venous return (preload) and causing hypotension. If patients have high FiO₂ and PEEP requirements and are developing ARDS, the use of high-frequency oscillatory ventilation (HFOV), while controversial, may be considered [24, 25]. HFOV is a mode of ventilation that delivers small tidal volumes at high frequencies in order to

Table 2 Classification of respiratory failure

	Type I: acute hypoxemic respiratory failure	Type II: hypercapnic	Type III: postoperative	Type IV: shock
Pathophysiology	Alveolar flooding Alveolar collapse	Decreased respiratory drive Increased respiratory workload Decreased respiratory muscle strength	Atelectasis (pain) Decreased respiratory drive from analgesics (narcotics)	Inadequate respiratory muscle perfusion with increased metabolic demands
Therapy	High FiO_2 PEEP Decrease pulmonary edema Treat pneumonia	Wake up/allow drugs to wear off Bronchodilators and suctioning Increase respiratory muscle endurance Correct metabolic abnormalities Intubation or NIPPV	Pain control Chest physical therapy Elevate head of bed	Treat underlying cause of the shock state Ventilator support
Overdose scenarios	Hydrocarbon aspiration, salicylates	Sedative overdose including narcotic or benzodiazepine overdose Bronchospasm Botulism	Not applicable	BB or CCA overdose Sepsis Mitochondrial inhibition

BB β -adrenergic blocking agents, CCA calcium channel antagonists, FiO_2 fraction of inspired oxygen, NIPPV noninvasive positive pressure ventilation, PEEP positive end-expiratory pressure

maintain alveolar recruitment while avoiding injury from barotrauma [26]. Further details regarding the pathophysiology and management of ARDS can be found in ► [Chap. 16, “Treatment of Acute Respiratory Distress Syndrome in the Poisoned Patient”](#).

When type II (hypercapnic) respiratory failure is caused by decreased respiratory drive, minute volume (V_E) provided by the ventilator must be sufficient to maintain alveolar ventilation. Respiratory load and respiratory muscle strength are connected inseparably. Bronchoconstriction and increased secretions increase respiratory load. Impaired neuromuscular transmission or respiratory muscle problems (e.g., botulism, myopathy, or overuse fatigue) decrease respiratory muscle strength. If respiratory load increases or strength decreases to the point at which load is greater than strength, type II respiratory failure ensues. Treatment of increased respiratory load includes the

use of bronchodilators and frequent suctioning. Muscle strength can be increased by treatment of underlying causes and ventilator support until respiratory muscle strength has returned. Therapy for type IV respiratory failure is to provide ventilatory assistance while treating the shock state.

The ventilator mode to be used is dictated by the type of respiratory failure. In general, patients with type I (hypoxemic) or type IV (shock) respiratory failure should be managed with an assist/control (A/C) or continuous mandatory ventilation (CMV) mode, which decreases the patient's work of breathing (Level III recommendation). Use of A/C or CMV decreases but does not eliminate respiratory muscle work and decreases the patient's oxygen and metabolic requirements. The decreased oxygen requirement is particularly important when oxygen transfer from the airways to the blood is impaired (aspiration) or there is inadequate oxygen delivery (shock). Type II

(hypercapnic) respiratory failure typically is seen with drug-induced coma or paralysis and is managed with either a CMV or a synchronized intermittent mandatory ventilation (SIMV) mode (Level III recommendation). If the drug-induced coma or respiratory depression is from narcotics or benzodiazepines, administration of naloxone or flumazenil, respectively, will improve the patient's ventilatory function and can prevent the need for intubation (Level II-3 recommendation). The risks and benefits of administering naloxone or flumazenil should be carefully weighed when administering them to patients with chronic use of either opioids or benzodiazepines. If the patient is already intubated, naloxone or flumazenil should generally be avoided. However in patients that were intubated but known to have ingested opioids or benzodiazepines, reversal agents may allow the patient to be extubated sooner. In addition, these agents may be useful to reverse iatrogenic sedation that prolongs the time that the patient is intubated. Decreasing the duration of time that the patient is intubated may decrease ventilator-associated complications.

Patient workload in a patient-triggered SIMV mode has been shown to range from 49% to 118% of the workload expected from a spontaneously breathing subject [27, 28]. This is important because if the patient's type II (hypercapnic) respiratory failure is from muscular weakness, the use of the SIMV mode can exacerbate the muscular weakness and prolong time on the ventilator. If there is increased respiratory load from bronchoconstriction, care must be taken to avoid air trapping within the lung. Commonly called *auto-PEEP*, this dynamic hyperinflation of the lung occurs when a breath is delivered to the patient before the previous breath is completely exhaled. Adverse effects of *auto-PEEP* include hypotension, pulmonary barotrauma (e.g., pneumothorax), and ARDS. *Auto-PEEP* can be minimized by decreasing inspiratory time and maximizing expiratory time (i.e., decreasing the I:E ratio) and use of small tidal volumes (V_T), slow respiratory rates, and increased flow rates. If the provider is concerned about air trapping and *auto-PEEP*, they should check the plateau pressure or the alveolar pressure; it should be below

30 cm H_2O . If air trapping is present, the patient should be immediately removed from the ventilator and have their chest manually decompressed before being placed back on the ventilator with new settings.

When the patient has been intubated and initial ventilator settings chosen, further information may be obtained from serial arterial blood gas measurements, bedside observations, and patient-ventilator interactions. Arterial blood gases (ABGs) assess the patient's acid-base status, arterial oxygenation, and ventilation. Venous blood gases (VBGs) can also assess the acid-base status and ventilation but not oxygenation. Initiation of mechanical ventilation may cause rapid deterioration in some poisoned patients if appropriate V_E , $PaCO_2$, and pH are not maintained. Intoxicants such as salicylates, methanol, and ethylene glycol produce severe, life-threatening acidosis for which the patient naturally compensates with a respiratory alkalosis. If the patient is well sedated, paralyzed, or fatigued, he or she may not be able to increase V_E to compensate for a metabolic acidosis. When the amount of V_E set on the ventilator is less than the V_E the patient was maintaining before intubation, significant acid-base changes may occur and precipitate disastrous events. Loss of compensatory respiratory alkalosis in salicylate intoxication causes acidemia and further movement of salicylate into the central nervous system that may precipitate seizures and death. While intubation may still be indicated, the physician must be vigilant in adjusting the ventilator settings to maintain appropriate ventilation. In the setting of salicylate intoxication, for instance, the rate should be set to match the patient's peak respiratory rate. It is important to monitor ABGs and make appropriate ventilator changes to keep pH, $PaCO_2$, and PaO_2 in the desired ranges.

When determining the ventilator settings, a lung protective strategy should be employed [29, 30]. Lung protective strategies prevent the development of ARDS from barotrauma and oxygen toxicity (Level II-2 recommendation). While these strategies are commonly used in the ICU, they have not been studied in the poisoned patient. Many intoxicated patients are intubated for

reasons other than for an acute lung injury (e.g., respiratory depression, altered mental status, delirium). In these situations, the FiO_2 should be titrated down as long as the PaO_2 remains greater than 90 mmHg. The patient's initial V_T should be set to 6 ml/kg and titrated based on their ABG and oxygen saturation in order to avoid barotrauma and toxicity from hyperoxygenation.

Frequent physical examination is necessary to evaluate the patient's comfort and interactions with the ventilator. If the patient is not synchronizing well with the ventilator, the cause of the patient's discomfort should be investigated. Ventilator settings must be adjusted to stabilize and comfort the patient rather than reflexively increasing sedation or paralyzing the patient. In addition, it should be ensured that the patient is receiving adequate analgesia. The endotracheal tube and ventilator are painful and most sedatives do not control pain. With adequate analgesia, most patients remain lightly sedated and synchronize well with the ventilator. In addition to improving patient comfort, proper administration of analgesics can decrease the patient's sedative requirement, preventing delirium and other complications. Much information can be obtained by observing the patient's pattern of breathing. Most ventilators display airway pressure versus time and flow versus time waveforms. Careful analysis of these waveforms yields important clues as to the cause of the patient's discomfort [31]. Waveform analysis is beyond the scope of this chapter and can be achieved best with the help of an experienced intensivist. Some maneuvers that can make the patient more comfortable on the ventilator include increasing V_E (by increasing V_T , respiratory rate, or both), decreasing triggering sensitivity or switching to flow triggering, and increasing flow rates [28]. Other maneuvers include treating pain, anxiety, and derangements of gas exchange or respiratory mechanics [31]. When these changes fail to match the ventilator to the patient, judicious use of sedation is required. Paralysis in poisoned patients usually is only reserved for specific indications (discussed later).

Circulation and Hemodynamics

After establishing an airway and supporting respiratory function, the next priority is assessment of circulatory status. In the poisoned patient, cardiovascular abnormalities commonly seen are hypertension, hypotension, cardiac arrhythmias, or conduction disturbances.

Hypertension

Elevated blood pressure in the poisoned patient may or may not be the result of exposure to any one of many substances (Table 3). Other causes of elevated blood pressure should be considered and include [1] withdrawal (i.e., benzodiazepine or ethanol withdrawal); [2] the discontinuation of a therapeutically prescribed medication, such as clonidine or minoxidil, causing rebound hypertension; and [3] inadequately treated or untreated underlying hypertension.

Treatment of hypertension is determined by its underlying cause. When hypertension is caused by overdoses of drugs with direct adrenergic activity, such as amphetamines, ephedrine, or pseudoephedrine, direct vasodilators, such as phentolamine or nitroprusside [32], may be required (Level III recommendation). Other commonly used agents include short-acting dihydropyridine calcium channel antagonists, such as nifedipine and clevidipine. When hypertension is caused by drugs with indirect adrenergic activity or by drug-of-abuse withdrawal, sedation with benzodiazepines [33, 34] may be the treatment of choice (Level II-2 recommendation). Pharmaceutical drug withdrawal can be treated by the reinstitution of the causative agent or use of another agent that attenuates the signs and symptoms. The physiology and treatment of withdrawal states are described in detail in ► Chap. 27, "Withdrawal Syndromes". Combining direct vasodilators, such as oral nifedipine or parenteral nitroprusside, and sedatives may be necessary in cases of severe hypertension resulting from any cause. For sympathomimetic-induced hypertension, such as seen with

LSD lysergic acid diethylamide, PCP phenylcyclohexyl piperidine

cocaine or amphetamines, administration of a β -adrenergic blocker alone may cause unopposed α -adrenergic stimulation and worsen hypertension (Level III recommendation). Large ingestions of α -2 agonists can initially cause hypertension. However, this is temporary and the patient is at risk of becoming hypotensive. If hypertension from α -2 agonists is treated, only short-acting agents that can be rapidly removed (e.g., nicardipine, nitroglycerin) should be administered (Level III recommendation).

Hypotension and Shock

Shock is the inability to deliver oxygen at a cellular level where the consumption of oxygen (VO_2) is greater than the delivery of oxygen (DO_2) [35]. Clinically, it appears as the constellation of hypotension, tachycardia, decreased or altered mentation, and oliguria or anuria. Laboratory values consistent with dysfunction of aerobic metabolism include hyperlactatemia and metabolic acidosis. Of patients who receive fluid resuscitation for shock, 85% have inadequate oxygen delivery to the tissues despite normalization of vital signs and urine output, referred to as cryptogenic shock [36]. Cryptogenic shock is diagnosed by biomarkers such as serial lactic acid concentrations and either ABGs or VBGs. The goal of circulatory resuscitation is to return VO_2 and DO_2 to normal and not simply to “fix the vital signs.”

The initial assessment of the poisoned patient in shock is to determine the physiologic cause of the inadequate DO_2 . DO_2 is the product of arterial oxygen content (CaO_2) and cardiac output (Q_T):

$$\text{DO}_2 = \text{CaO}_2 \times Q_T$$

CaO_2 is determined primarily by hemoglobin concentration and saturation:

$$\begin{aligned} \text{CaO}_2 = & (1.39 \text{ mL O}_2/\text{g hemoglobin} \\ & \times \text{g hemoglobin/dL} \times \text{SaO}_2) \\ & + (0.0031 \text{ mL/dL/mmHg} \times \text{PaO}_2) \end{aligned}$$

Cardiac output (Q_T) is the product of heart rate (HR) and stroke volume (SV):

$$Q_T = \text{HR}(\text{beats/min}) \times \text{SV}(\text{mL/beat})$$

SV is determined by left ventricular preload, contractility, and afterload. Physiologic causes of inadequate DO_2 in the poisoned patient may be the result of decreased hemoglobin concentration or saturation, decreased left ventricular preload (hypovolemia), decreased afterload (vasodilation), or impaired cardiac contractility.

Interruption of oxygen use at the molecular level is another cause of inadequate DO_2 in the poisoned patient. Specifically, abnormal hemoglobins (i.e., methemoglobin, sulfhemoglobin, or carboxyhemoglobin [37–39]) and toxins that disrupt the mitochondrial electron transport chain (e.g., cyanide, hydrogen sulfide, or sodium azide [40–42]) prevent the use of oxygen at the molecular level. Ineffective oxygen use may also occur from the disruption of metabolic processes, such as the uncoupling of oxidative phosphorylation (e.g., salicylate and dinitrophenol ingestions). In addition, impairment of the redox potential (NAD:NADH) disrupts oxidative processes as can occur from ethanol. Elevated plasma lactate concentration accompanying a metabolic acidosis is often a marker of these toxicities. It is a by-product of anaerobic metabolism of glucose when pyruvate is shunted to lactic acid [43].

Lactic acidosis develops from an inequality between the production and breakdown of lactate, which is normally cleared by the liver and kidneys [44]. There are two forms of lactic acidosis as classified by Cohen and Woods in 1976 (Table 4) [45]. Type A lactic acidosis occurs from inadequate oxygen delivery [46]. While more common than Type B, both can be present at the same time. Carbon monoxide is an example of a toxicant producing a Type A lactic acidosis. Type B lactic acidosis occurs without evidence of poor tissue perfusion or oxygenation and is classified into 3 subtypes [47, 48]. Subtype B1 occurs with systemic disease (e.g., malignancy, ketoacidosis); type B2 is from medications, drugs, or toxicants; and type B3 is from inborn errors of metabolism.

Table 4 Causes of lactic acidosis

Hypoxic (Type A)	Non-hypoxic (Type B)
Ischemia (e.g., cardiac arrest)	Delayed clearance (e.g., hepatic dysfunction)
Global hypoxia (e.g., carbon monoxide)	Pyruvate dehydrogenase dysfunction (e.g., thiamine depletion)
Respiratory failure (e.g., asthma)	Uncoupling of oxidative dysfunction (e.g., salicylates)
Regional hypoperfusion (e.g., mesenteric ischemia)	Accelerated aerobic glycolysis (e.g., seizures)

Examples of toxicants that produce a type B lactic acidosis include uncouplers (e.g., salicylates, dinitrophenol), biguanides such as metformin, and methanol. The normal plasma lactate concentration is 0.5–1 mmol/L (4.5–9 mg/dl). Hyperlactatemia is defined as a concentration between 2 and 4 mmol/L (18–36 mg/dl) without a metabolic acidosis, while lactic acidosis is defined as a concentration greater than 5 mmol/L (45 mg/dl) with a metabolic acidosis [47]. Mortality is increased nearly threefold when lactic acidosis accompanies low-flow states with higher lactate concentrations associated with worse outcomes [49, 50]. A case-control study evaluated serum lactate concentration in drug overdoses at two urban teaching hospitals that were affiliated with a regional poison center [51]. Controls included consecutive drug overdoses admitted over a 1-year period surviving until hospital discharge. Cases were patients admitted over a 7-year period who died. The study consisted of 50 cases and 100 controls. The mean lactate concentration was 9.88 ± 6.7 mmol/L (89 mg/dl) for cases and 2.76 ± 2.9 mmol/L (25 mg/dl) for controls ($p < 0.001$). A lactate concentration of 3.0 mmol/L (27 mg/dl) conferred a 15.8-fold increase in odds of fatality ($p < 0.001$). Serum lactate concentrations were also evaluated in an 8-year retrospective review of all 110 β -adrenergic antagonist overdoses admitted to an ICU [52]. Serum lactate concentration (median 1.79 mmol/L; 10–90% percentiles 0.8–5.6) (19 mg/dl [7.2–50.5]) was the most significantly different parameter on admission between

survivors and fatalities ($p = 0.0008$). Six patients who presented with lactate concentrations >6 mmol/L (45 mg/dl) had prolonged prehospital cardiac arrests. Four patients died in the ICU despite lactate concentrations under 3.0 mmol/L (27 mg/dl). While a lactate >3 mmol/L (27 mg/dl) was associated with a 5.4-fold increased odd of mortality (OR 5.4, 95% CI 1.3–22.0), it only had a sensitivity of 55%, specificity of 80%, positive predictive value of 21%, negative predictive value of 95%, and an accuracy of 78%. The authors concluded that while serum lactate concentrations are useful, caution should be applied when using them to predict final outcome.

Decreased hemoglobin concentration may be the result of GI bleeding (e.g., gastric erosions from iron or nonsteroidal anti-inflammatory drug ingestion), intravascular hemolysis (e.g., arsine gas exposure), decreased production (e.g., benzene), or various chronic medical conditions (e.g., renal failure or cancer). Hemoglobin concentration is easily measured, and the administration of blood products may be indicated while the cause of the anemia is investigated. In acute bleeds, hemoglobin concentrations can be initially falsely elevated. While not studied in poisoned patients, recent studies advocate for conservative transfusion strategies in patients not in shock [53, 54]. When patients on anticoagulants are hemorrhaging, they should be reversed. Vitamin K antagonists (e.g., warfarin) can be reversed with fresh frozen plasma (FFP) or prothrombin complex concentrate (PCC). Advantages of PCC include smaller volume and faster reversal. Unfortunately, it is more expensive and is associated with thrombotic complications [55]. Patients on newer oral anticoagulants are more difficult to treat as it is unclear if they can be reversed. Dabigatran-related hemorrhage can be reversed with idarucizumab [56, 57]. Other potential reversal modalities include PCC and hemodialysis [58, 59]. While not currently approved, andexanet alfa is being studied to reverse hemorrhage from factor Xa inhibitors (e.g., apixaban and rivaroxaban) [60]. A full discussion of the management of significant bleeding from oral anticoagulants can be found in ► Chap. 68, “Oral Anticoagulants.” Causes and treatment of decreased hemoglobin

saturation were addressed previously in the discussion of type I respiratory failure (see Table 2).

Hypovolemia in the poisoned patient may be caused by GI losses (e.g., organophosphates, cathartics, bleeding), renal losses (e.g., lithium or diuretics), redistribution (e.g., caustic burns or snake envenomations), or increased insensible losses (e.g., fever from sympathomimetics or salicylates). Signs of hypovolemia include dry mucous membranes, narrow pulse pressure, decreased urine output, and low cardiac output. Certain vasodilated shock states, such as liver failure from either acetaminophen overdose or *Amanita* mushroom poisoning or thyroid storm following thyroxine overdose, present with a clinical picture more consistent with sepsis: hypotension, warm extremities, a wide pulse pressure, and increased cardiac output.

Cardiac Dysrhythmias and Conduction Abnormalities

Cardiac depression, dysrhythmias, cardiac conduction abnormalities, or a combination of all three may cause shock from *impaired cardiac contractility*. Impaired cardiac contractility may be caused by β -adrenergic blocking agents or cocaine-induced myocardial ischemia and manifests as hypotension, narrow pulse pressure, low cardiac output, jugular venous distention, a gallop rhythm, and crackles in the lungs. Crackles are not present on examination with patients in right heart failure with preserved left ventricular function.

An electrocardiogram should be obtained in poisoned patients to assess for dysrhythmias, cardiac conduction defects, heart rate, and wave intervals (PR, QRS, QT), which may give clues as to the poison, the severity of the poisoning, and the treatment (Level III recommendation). The relationships between heart rate, QRS duration, and possible causes are listed in Table 5. Specific therapies are reviewed in ► Chaps. 21, “Cardiac Conduction and Rate Disturbances”, and ► 22, “Toxicant-Induced Torsade de Pointes”, and in chapters dealing with individual toxicants.

Torsades de Pointes, a form of ventricular tachycardia associated with a long QT interval, also may impair cardiac output. Although other causes such as electrolyte abnormalities exist,

Table 5 Examples of xenobiotic association between heart rate and QRS duration

Heart rate	Narrow QRS complex	Wide QRS complex
Tachycardia	α -Adrenergic agonists	Aberrant conduction
	Amphetamines	Antihistamines
	Anticholinergic agents	Cocaine
	Theophylline	Propoxyphene Sodium channel blockers Thioridazine Tricyclic antidepressants
Bradycardia	α -Adrenergic lytic agents	β -Adrenergic blocking agents

	Sodium channel blockers (open)	
	Tetrodotoxin	

torsades des pointes is often drug related. Medications that cause torsades des pointes, its pathophysiology, and its treatment are reviewed in ► Chap. 22, “Toxicant-Induced Torsade de Pointes” and in Table 6.

Fluid Resuscitation

Fluid resuscitation of the poisoned patient must be individualized. Many patients, especially patients found in coma many hours after their ingestion, are volume depleted (e.g., GI losses, fever, insensible losses). Volume depletion usually is not the acute cause of shock in poisoned patients but may be a contributing cause. Shock may be caused by vasodilation, myocardial depression, chemically induced hemoglobinopathy, or a combination of these. The usual approach of administering fluids until clinical improvement (e.g., improved blood pressure, mentation, adequate urine output) or development of a complication (i.e., pulmonary edema or worsening gas exchange) should be

modified in the poisoned patient (Level III recommendation). Initial resuscitation measures should include the administration of intravenous crystalloid fluid, but when appropriate, vasopressor infusion should be started early in the course of the resuscitation. Vasopressors or inotropes may be more appropriate than continued fluid administration in poisoned patients with a distributive shock (e.g., from vasodilators) or cardiogenic shock (e.g., from negative inotropes). Some patients require the placement of a central venous catheter to determine cardiac filling status and to optimize fluid and vasopressor therapy. In addition, bedside sonography is used to determine volume responsiveness and estimate cardiac contractility to further guide resuscitation [61, 62].

The debate regarding the most effective fluid to be used in the resuscitation of poisoned patients parallels the debate in critical care medicine in general [63–66]. The ideal fluid would have a chemical composition similar to that of extracellular fluid, would not accumulate in tissues, would not cause adverse metabolic effects, and is cost-effective [67]. Resuscitation fluids are broadly categorized as either colloid or crystalloid solutions. Colloids are suspensions of molecules within a carrier solution that are relatively incapable of crossing the capillary membrane, while crystalloids are ionic solutions that are freely permeable [67]. Fluids that provide oncotic pressure (e.g., albumin, fresh frozen plasma, hetastarch) and stay in the intravascular space longer than crystalloids theoretically are preferred

[68]. However, current evidence does not demonstrate improved clinical outcomes with colloids as opposed to crystalloids; as such, crystalloids should be used to resuscitate patients [69–71] (Level I recommendation). The infusion of packed red blood cells in patients with decreased hemoglobin concentrations increases plasma volume, CaO_2 , and QO_2 . As previously discussed, recent studies advocate for conservative transfusion strategies in patients not in shock [53, 54].

Colloids can be divided into albumin and semi-synthetic colloid solutions (hydroxyethyl starch [HES] and succinylated gelatin). Multiple trials have investigated albumin in the resuscitation of critically ill patients. A meta-analysis by the Cochrane Injuries Group compared albumin to crystalloid solutions or fluids without albumin in critically ill patients [66]. The analysis included 32 randomized controlled trials. In the study, albumin was associated with a significantly increased rate of death (relative risk [RR], 1.68; 95% CI 1.26–2.23; $p < 0.01$). An updated meta-analysis by the Cochrane Injuries Group in 2011 included 38 trials [72]. Albumin did not reduce mortality with a pooled RR of death of 1.05 (95% CI 0.95–1.16). The Saline versus Albumin Fluid Evaluation (SAFE) study was a blinded, randomized controlled study conducted in Australia and New Zealand [73]. Nearly 7,000 patients in ICUs in 16 different academic centers whom the treating physician judged to require fluid resuscitation were included. Mortality was compared in patients resuscitated with either 4% albumin or normal saline. Once again, albumin did not decrease mortality (RR 0.99; 95% CI 0.91–1.09; $p = 0.87$). In addition, the number of patients with new single-organ failure was similar between groups ($P = 0.85$ by Fisher's exact test). Albumin also did not decrease death at 28 days in the subgroups of patients with severe sepsis (RR 0.87; 95% CI 0.74–1.02; $p = 0.09$) or trauma without closed head injury (RR 1.00; 95% CI 0.56–1.79; $p = 1.00$). The Colloids Versus Crystalloids for the Resuscitation of the Critically Ill (CRISTAL) trial was a multicenter, randomized clinical trial comparing crystalloids to colloids in patients with hypovolemic shock in the ICU [69]. The amount of fluid received and duration of treatment were at

the discretion of the treating physician. A total of 2,857 patients were enrolled. At 28 days, there were 359 deaths (25.4%) in the colloids group compared to 390 deaths (27%) in the crystalloids group (RR 0.96; 95% CI 0.88–1.04; $p = 0.26$).

Hydroxyethyl starch solutions are the most commonly used semisynthetic colloids and are produced by hydroxyethyl substitution of amylopectin obtained from sorghum, maize, or potatoes [67]. Reduced concentrations (6%) of HES are currently used due to safety concerns from concentrated (10%) HES. In a blinded, randomized, controlled trial of 798 patients with severe sepsis in Scandinavia, HES was associated with an increase in mortality as compared to Ringer's acetate (RR 1.17; 95% CI 1.01–1.36; $p = 0.03$) [74]. More patients also required renal replacement therapy (RR 1.35; 95% CI 1.01–1.80; $p = 0.04$). A secondary analysis of this data demonstrated an increased rate of severe acute kidney injury and the use of renal replacement therapy within the first 5 days of treatment [75]. Given that colloids are more expensive and are not shown to improve outcomes, they cannot be recommended for the resuscitation of most critically ill patients (Level I recommendation). HES solutions should no longer be used in critically ill patients (Level I recommendation).

Crystalloids are used more frequently in poisoned patients because they are readily available, are much cheaper, do not carry the risk of disease transmission seen with blood products, and are as effective as oncotic agents. While crystalloids should be used to resuscitate poisoned patients, practitioners should consider using a “balanced fluid” resuscitation strategy (Level II-2 recommendation). “Balanced fluids” contain organic anions such as lactate and have a lower chloride content more closely resembling the composition of normal plasma [76]. In “balanced fluids,” the difference between the strong cations and the strong anions in the fluid will be between 24 and 28, which once dilutional changes are accounted for is similar to plasma. Examples of “balanced fluids” include lactated Ringer's and PlasmaLyte; chloride-rich solutions such as normal saline are not balanced. To determine if a solution is balanced, use the strong ion difference or SID and

compare it to a patient's bicarbonate. If the SID is less than the patient's bicarbonate, the fluid will be acidotic; if the SID is greater than the patient's bicarbonate, the fluid will be alkalotic. As an example in normal saline, the difference between the Na and Cl is 0 ($154 - 154 = 0$). In a patient with a normal bicarbonate concentration (24 mEq/L), the bicarbonate is greater than the SID and so the fluid will essentially be acidotic [77]. This is the etiology of the non-anion gap metabolic acidosis in patients that receive normal saline. In comparison, lactated Ringer's has a SID of 21, which is much more similar to a patient's normal serum bicarbonate of 24 mEq/L and, therefore, much less likely to cause a metabolic acidosis. The topic of strong ion differences is reviewed in greater detail in ► [Chap. 15, “Acid–Base Balance in the Poisoned Patient”](#).

Recent literature indicates that patients that receive large volumes of “unbalanced solutions” have increased morbidity and mortality, although none of these trials have included poisoned patients. A large retrospective cohort study compared patients undergoing either elective or emergent open general surgical operations that received either NS or a balanced fluid the day of the procedure [78]. Unadjusted in-hospital mortality (5.6% CI 5.3–5.8 vs. 2.9% CI 2.0–4.2; $p < 0.001$) and the number of patients developing major complications (33.7 vs. 23%) were significantly greater in the group that received NS compared to the group that received balanced crystalloids. After using propensity scoring to correct for multiple variables, the difference in mortality was no longer significantly different; however, patients that received NS were 4.8 times more likely to require dialysis ($p < 0.001$). Additionally, patients requiring emergent general surgery showed an adjusted odds of death nearly 50% less in the cohort that received a balanced resuscitation compared to NS (OR 0.51 CI 0.28–0.95). In a prospective, open-label study of consecutive patients admitted to an ICU, those that received balanced crystalloids had a lower incidence of acute kidney injury (OR 0.52 CI 0.37–0.75; $p < 0.001$) and less need for renal replacement therapy (OR 0.52 CI 0.33–0.81; $p = 0.004$) [79]. Septic patients also had a trend

toward lower mortality when resuscitated with balanced fluids as opposed to normal saline (OR 0.78; 95% credibility intervals 0.58–1.05) [80].

Current evidence indicates that balanced crystalloid fluids should be administered for rapid volume expansion during an acute resuscitation of a critically ill patient. However, different factors need to be considered in regard to the administration of maintenance fluids in these patients. While large amounts of crystalloid solution containing high chloride concentrations are associated with deleterious effects, this may not apply to maintenance fluids, where much less volume is administered. Maintenance fluids are used to preserve the extracellular volume while maintaining a normal electrolyte balance and preventing dehydration [81]. In this context, fluids are either isotonic (sodium concentration approximately equal to plasma sodium concentration) or hypotonic (sodium concentration is less than that of plasma). Dextrose-containing solutions, while they may be hyperosmolar, are not hypertonic as the glucose is rapidly metabolized.

Traditionally, hypotonic solutions were administered to both adults and children [82, 83]. Isotonic solutions were avoided due to concerns for the development of volume overload, hyponatremia, and hypertension. However, hypotonic solutions cause hyponatremia, which many critically ill patients are already at risk of developing due to either dysregulation of sodium and water homeostasis or medication-induced syndrome of inappropriate antidiuresis. In addition to normal triggers for the release of arginine vasopressin (AVP) such as hypovolemia and hypotension, pain, stress, nausea and vomiting, hypoxemia, hypercapnia, and hypoglycemia all stimulate the release of AVP, which impairs excretion of free water and causes hyponatremia [84]. Hyponatremia affects approximately 15–30% of hospitalized patients and is generally related to the administration of hypotonic fluids in patients with elevated AVP concentrations [85, 86]. The development of hyponatremia is linked to an increase in mortality [87].

Isotonic solutions are now recommended as maintenance fluids in both adults and children

[88, 89] (Level I recommendation). While mainly investigated in pediatrics, more than 15 randomized, prospective trials involving more than 2000 patients have evaluated the safety and efficacy of isotonic fluids compared to hypotonic fluids as maintenance fluids [81]. A meta-analysis involving nearly 1000 children associated hypotonic fluids with a RR of 2.37 for the development of mild hyponatremia (<135 mmol per liter) and a RR of 6.2 for moderate hyponatremia (<130 mmol per liter) [90]. A Cochrane review compared the development of hyponatremia in patients receiving maintenance fluids composed of either isotonic or hypotonic solutions [91]. Ten studies with a total of 1106 patients were included in the review. Patients that received isotonic fluids had a lower risk of developing hyponatremia compared to those receiving hypotonic fluids (17% vs. 34%; RR 0.48; 95% CI 0.38–0.60). Importantly, many of the studies followed patients for less than 72 h, and patients with renal disease, heart disease, or cirrhosis were often excluded. In addition, the majority of patients were children. While little information exists regarding the most appropriate therapy in edematous states, isotonic fluids at a restricted rate are recommended in these patients [81].

Vasoactive Agents

The usual ICU approach to a patient with adequate fluid resuscitation and inadequate cardiac contractility is the administration of dobutamine or norepinephrine. However, the vasodilatory properties of dobutamine may worsen hypotension in a hypovolemic patient, which again stresses the need for optimal fluid resuscitation. Although norepinephrine increases mean arterial pressure, the increased afterload produced by infusion of norepinephrine may decrease cardiac output. Dopamine is considered to be a third-line agent for treating depressed cardiac contractility owing to its mixed α - and β -effects and indirect mechanism of action. However, it is still used in many pediatric intensive care units. Dopamine stimulates different adrenergic receptors at different infusion rates: dopaminergic at 1–3 $\mu\text{g/kg/min}$, β -adrenergic at 5–10 $\mu\text{g/kg/min}$, and α -adrenergic at 10–20 $\mu\text{g/kg/min}$. Further,

individual variability in response to dopamine infusions precludes the ability to predict which subset of adrenergic receptors is stimulated at a given dose of dopamine in a specific individual. Because part of dopamine's vasopressor effect is through the release of norepinephrine, dopamine has decreased efficacy in norepinephrine-depleted states, such as cyclic antidepressant toxicity [92]. Due to this mechanism, many medical toxicologists prefer the use of a direct-acting vasopressor such as norepinephrine as first-line treatment. If stimulation of β -receptors is desired, dobutamine is theoretically advisable. Norepinephrine is preferable to phenylephrine to stimulate α -receptors. Despite these considerations, the agent of choice is the one that works best for the individual patient and may not be predicted based on the abovementioned theoretical considerations. One multicenter, randomized trial compared norepinephrine to dopamine in patients with shock from multiple etiologies [93]. No difference in mortality was found between the two agents, although dopamine was associated with a greater incidence of arrhythmic events. No poisoned patients were included in the study.

There are very little data regarding the optimal adrenergic vasoactive agents in poisoned patients [94]. Case reports and retrospective case series imply that TCA-related hypotension may be more responsive to norepinephrine than dopamine [95, 96]. In a dog model, TCA-induced hypotension was equally responsive to dopamine and norepinephrine. Only high-dose dopamine infusions of 15 $\mu\text{g}/\text{kg}/\text{min}$ or higher (α -range) were as effective, however, as low doses of norepinephrine (0.25 $\mu\text{g}/\text{kg}/\text{min}$) [97]. There is some evidence that norepinephrine may be the initial vasopressor of choice for TCA-induced hypotension [96]. In a retrospective analysis of 26 adults with TCA-associated hypotension, all patients responded to norepinephrine ($n=11$), while only 60% of patients adequately responded to dopamine ($p=0.02$). A single toxicology inpatient service retrospectively reviewed their management of 48 patients following an overdose of either verapamil or diltiazem; 33 (69%) received a vasopressor [98]. No patients died after vasopressors were initiated, even though many patients

required high doses of vasopressors or multiple vasopressors (median 2; range 1–5). While direct comparisons between agents were not made, vasopressor use was associated with good outcomes with few ischemic complications.

Because of lack of data, the choice of pressor must be made on clinical and theoretical grounds. Contrary to some dogmatic beliefs, all vasopressors can initially be administered peripherally while central access is obtained [99]. Due to familiarity, traditional practice, and the belief that extravasation injuries from peripherally administered dopamine are less severe than from other vasopressors, dopamine is often the preferred agent in pediatric patients. Considerations for different xenobiotics or toxicants are reviewed in their respective chapters.

Nonadrenergic vasoactive drugs are an effective therapy for shock caused by β -adrenergic blocking agents and calcium channel antagonists (Level III recommendation). Glucagon stimulates adenylyl cyclase, which increases intracellular cyclic adenosine monophosphate (cAMP) through a nonadrenergic mechanism. The increased cAMP causes an increase in intracellular calcium, which leads to positive chronotropic and inotropic actions. Glucagon improves cardiac index, urine output, and symptoms in patients with chronic congestive heart failure [100]. Numerous case reports and laboratory investigations describe glucagon's effectiveness in reversing hypotension caused by overdoses of β -adrenergic blocking agents and calcium channel antagonists, although its mechanism of action would seem to make its effectiveness in calcium channel antagonists less likely than in overdoses from β -adrenergic blocking agents [101–104]. There are also reports of glucagon reversing TCA-induced hypotension [105, 106]. In overdose patients, glucagon can be considered in hypotension unresponsive to the usual pressors (Level III recommendation). A glucagon dose of 5–10 mg administered intravenously over 10 min should be followed by a glucagon infusion (3–15 mg/h). An antiemetic should be provided with glucagon as it decreases lower esophageal tone which causes emesis. Inamrinone, a phosphodiesterase type III inhibitor formerly known

as amrinone, prevents the breakdown of intracellular cAMP. Inamrinone administration has been reported to reverse hypotension in overdoses of calcium channel antagonists [107], chloroquine [108], and propranolol [109]. It has also reversed hypotension in calcium channel antagonist overdoses in animals [110, 111]. Milrinone, another phosphodiesterase type III inhibitor, was used in the treatment of a patient with venlafaxine-associated cardiomyopathy; this patient required milrinone for 12 days in addition to multiple other therapies [112]. Milrinone was also studied in a dog model [113]. Because phosphodiesterase inhibitors have direct peripheral vasodilatory properties, however, further worsening of hypotension may occur if the decrease in blood pressure from vasodilation is greater than the increase in blood pressure from improved cardiac output. They should be used cautiously, if at all, with continuous bedside monitoring.

More recently, high-dose insulin euglycemia therapy (HIE) was used to treat hypotension and cardiac dysfunction from β -adrenergic blocking agents and calcium channel antagonists. In overdose, calcium channel antagonists decrease insulin release from pancreatic β -cells, cause insulin resistance in the myocardium, and change myocyte metabolism from fatty acids to carbohydrates [114]. Under stressful conditions such as in shock from both β -adrenergic blocking agents and calcium channel antagonists, the myocardium changes its preferred energy substrate from fatty acids to carbohydrates [114, 115]. High-dose insulin euglycemia therapy improves myocyte use of carbohydrates as an energy source and, therefore, increases cardiac contractility and improves perfusion. In the laboratory, insulin infusions increase myocardial contractility, possibly through increases in intracellular calcium [116]. Compared with calcium chloride, epinephrine, and glucagon, HIE decreased mortality in dogs poisoned with verapamil [114, 116, 117]. In a swine model, HIE was more effective than epinephrine and vasopressin, combined [118]. An increasing amount of data supports the efficacy of insulin in poisoning from β -adrenergic blockers and calcium channel antagonists. Insulin-glucose therapy improved hemodynamic

parameters in five patients with calcium channel antagonist overdoses who were persistently hypotensive despite multiple therapies (calcium, atropine, glucagon, adrenergic agonists) [119]. All five patients survived. A 60-year-old male presented after ingesting 5.4 g of extended-release diltiazem [120]. His shock resolved after receiving HIE. One patient received 6 U/kg/h for 5 h with clinical improvement without experiencing an adverse event [121]. In a review of 78 patients with toxicity from either calcium channel antagonists or β -adrenergic blocking agents treated with HIE, 88% survived [115]. High-dose insulin euglycemia therapy was successfully used in another case series in 11 of 12 patients; the single fatality occurred in a patient 1 h after HIE was discontinued in favor of vasopressor therapy [122].

Based on current knowledge, insulin and glucose infusion should be used in shock caused by calcium channel antagonists and β -adrenergic blocking agents that is unresponsive to fluid resuscitation [123] (Level III recommendation). While glucagon can be considered in shock from β -adrenergic blocking agents in the author's opinion, many practicing medical toxicologists prefer HIE or vasopressors, instead. The dosing of HIE generally used is a bolus of 1 U/kg of regular insulin with 0.5 g/kg of dextrose, followed by an infusion of 1 U/kg/h of insulin titrated to effect. There are reports of patients receiving infusions as high as 22 U/kg/h [115]. To prevent hypoglycemia, glucose infusions should accompany insulin infusions. Plasma potassium concentrations should be closely monitored while the patient is receiving HIE. Consideration can be given to even initiating HIE prior to other therapies such as vasopressors. The clinical pharmacology of HIE is discussed in ► [Chap. 147, "Euglycemic Insulin Therapy."](#) Its clinical use is discussed in greater detail in chapters on specific agents.

Limited evidence also supports the use of methylene blue in the treatment of shock from calcium channel antagonists [124, 125]. In a single case report, methylene blue was successfully used in a mixed atenolol and amlodipine ingestion [126]. Amlodipine stimulates the release of nitric oxide, thereby causing vasodilation and

worsening hypotension. Methylene blue acts as a nitric oxide scavenger. In addition, it inhibits nitric oxide synthesis and decreases the production of cyclic guanosine monophosphate production, which is generated by nitric oxide and increases vasodilation. Given the limited experience with methylene blue, it should not be viewed as a therapy to be used routinely in calcium channel antagonist toxicity. Based on current evidence, the author recommends that it be used in cases of refractory circulatory shock due to amlodipine toxicity.

Calcium sensitizers (e.g., levosimendan) have been proposed to treat shock from calcium channel antagonists. They act as inotropic agents and increase the association of myosin and actin cross-bridges while slowing down their dissociation rate [127]. In patients with congestive heart failure, they decrease afterload while increasing cardiac contractility and output. Case reports describe levosimendan reversing shock from calcium channel antagonists [128–130]. However, the overall evidence is still limited and these agents are not currently available in the United States or in many other countries.

Lipid Emulsion Therapy

The administration of lipid emulsion therapy (LET) is one of the most recent advances in the care of the critically ill poisoned patient. Originally investigated as a treatment for patients with local anesthetic toxicity, it has since been used in the management of toxicity from other xenobiotics [131]. Its mechanism of action is still not fully understood. The most accepted theory is that LET acts as a lipid sink and binds “lipid-soluble” xenobiotics removing them from their site of toxicity [132]. While there are multiple successful reports of LET reversing toxicity from lipophilic xenobiotics (e.g., calcium channel antagonists [133], tricyclic antidepressants [134]), there are also reports of its effectiveness in reversing toxicity from xenobiotics that are not lipophilic [135]. Other potential mechanisms of action include improving intracellular metabolism and ion channel activation.

Lipid emulsion therapy was first used in nonlocal anesthetic toxicity to resuscitate a

17-year-old with cardiovascular collapse following an ingestion of bupropion and lamotrigine [136]. Since then, there are many reports of LET successfully reversing toxicity from multiple agents (e.g., atenolol [135], diphenhydramine [137], quetiapine [138], cocaine [139], venlafaxine [140]). However, it is important to recognize that these anecdotal reports cannot be used to validate the efficacy of LET and are undoubtedly vulnerable to publication bias as unsuccessful use of LET in critically ill patients is unlikely to be reported.

A case series from the Toxicology Investigators’ Consortium (ToxIC) identified nine patients with presumed non-survivable cardiac toxicity (either cardiac arrest or hypotension refractory to vasopressors) that received LET [141]. Five of the patients survived including two patients in cardiac arrest; eighty percent of survivors were neurologically intact. Adverse effects associated with LET include DVT, pancreatitis, and laboratory interferences [141, 142]. As such, there is still disagreement as to if and when to administer LET. The position of the American College of Medical Toxicology (ACMT) is that there is no standard of care in regard to the use of LET, but if and when it is administered, it should be as a 20% lipid emulsion as a 1.5 ml/kg bolus followed by an infusion of 0.25 ml/kg/min [143] (Level III recommendation). LET is further discussed in ► [Chap. 152, “Lipid Resuscitation Therapy”](#) and in chapters dealing with specific relevant agents.

Extracorporeal Membrane Oxygenation

In venoarterial extracorporeal membrane oxygenation (ECMO), either the right atrium or ventricle is cannulated. Hypoxic blood is pumped through an oxygenator and returned to the systemic circulation via a central arterial catheter. Extracorporeal membrane oxygenation is indicated in poisoned patients in refractory shock that are failing conventional treatment [144] (Level III recommendation). There are multiple reports of poisoned patients successfully resuscitated with ECMO [145, 146]. In a retrospective review of poisoned patients in arrest or shock, mortality was improved in those that received ECMO (12/14) compared to those that did not (23/48) (86%

vs. 48%, $p < 0.02$) [147]. In many cases, poisoned patients are ideal candidates for ECMO as they tend to be otherwise healthy and are suffering from a reversible illness. In these patients, ECMO serves as a bridge until the toxic xenobiotic is metabolized or eliminated, at which time the patient should regain normal cardiovascular function. While adverse events are associated with ECMO, recent advances in technology have made this a more practical alternative during emergency resuscitation of critically ill patients [148]. The use of ECMO in poisoned patients is further discussed in ► Chap. 4, “Extracorporeal Membrane Oxygenation and Cardiopulmonary Bypass in the Poisoned Patient.”

Overdose and Cardiac Arrest

Few studies specifically address the issue of cardiac arrest as a direct consequence of poisoning. The AAPCC reported 1,835 exposure-related fatalities in 2014 [2]. The fatalities involved single substances in 42% of cases, two substances in 25% of cases, and three or more substances in the remainder of cases. There were 88 deaths in children (<20 years old), which was an 11.1% decrease from the previous year in that population; 16 deaths occurred in children less than 5 years old (1.4% of exposure-related fatalities). Nearly 66% of fatalities occurred in patients between 20 and 59 years of age. Only 2 deaths occurred in a pregnant patient. A recent analysis of data from the European Monitoring Centre for Drugs and Drug Addiction estimated that there were between 10,000 and 20,000 deaths a year in Europe from opioids [149]. In 2011, the average mortality rate due to overdoses in Europe was estimated at 18 deaths per million people aged 15–64 years old. Most countries reported an increase in overdose deaths from 2003 until 2009, when the number of deaths began to decline. Overall, there were approximately 6,500 overdose deaths reported in 2011. Over 19 years, there were 118 cases of cardiac arrest from intoxication at the Vienna General Hospital [150]. After resuscitation, 39 patients had a favorable outcome, defined as good neurologic

function or moderate disability on the Pittsburgh Cerebral Performance Category. However nearly a quarter of patients were arrested from opioid intoxication and nearly a third of patients were deteriorated and arrested in the hospital, so the results may have limited external validity. Autopsy findings revealed that only 76% of older adults and 25% of young adults had atherosclerotic coronary artery disease as a cause of cardiac arrest. This finding should influence the medical management of drug-induced cardiac arrest. Advanced Cardiac Life Support (ACLS) algorithms [151] should be altered when cardiac arrest, ventricular tachycardia, or ventricular fibrillation is caused by drug overdose because the mechanisms for these arrests are significantly different from the cardiovascular events for which ACLS protocols were created. Specific therapies, such as sodium bicarbonate, glucagon, HIE, LET, and ECMO should be considered. Tox-ACLS was specifically developed to incorporate differences in the resuscitation of the critically ill, poisoned patient [152]. The management of acute coronary syndrome with cocaine toxicity, cocaine-associated dysrhythmias, and opioid-induced respiratory failure with naloxone are examples of important topics covered in Tox-ACLS. The post-arrest management of these patients is discussed in greater detail in ► Chap. 5, “Post-Resuscitation Management of the Poisoned Patient.”

Invasive and Noninvasive Measurements of Hemodynamic Function

When patients are in shock, further information should be obtained to guide the resuscitation. Historically a pulmonary artery catheter (PAC), or Swan-Ganz catheter, was placed. Data obtained from a PAC includes central venous pressure, right ventricular pressure, pulmonary artery pressure, and left atrial pressure via the pulmonary capillary wedge pressure. Other data that can be obtained include oxygen saturation of mixed venous blood (SvO_2), thermodilution Q_T , systemic and pulmonary vascular resistance, QO_2 , shunt fraction (Q_S/Q_T), and VO_2 . However,

Table 7 Clinical uses of the pulmonary artery catheter

Determine etiology of shock state and assess efficacy of therapy
Assess intravascular volume
Renal failure, hypovolemia
Assess cardiac contractility
Cardiac output, mixed venous saturation (i.e., efficacy of therapy in CCA overdose)
Diagnosis of constrictive pericarditis or pericardial effusion
Waveform analysis
Measurement of pulmonary artery pressure
Pulmonary hypertension
Determine PCWP in the setting of pulmonary edema
High pressure (CHF) versus low pressure (ARDS) (i.e., hydrocarbon aspiration, toxic gas inhalation)
<i>ARDS</i> adult respiratory distress syndrome, <i>CCA</i> calcium channel antagonist, <i>CHF</i> congestive heart failure, <i>PCWP</i> pulmonary capillary wedge pressure

noninvasive monitoring techniques and a lack of an effect of PACs on outcome have sharply curtailed their use in poisoned patients. Some situations in which PACs may be useful are listed in Table 7. Because most overdose patients leave the ICU in 1–2 days, they rarely require a PAC and their use has not been studied in poisoned patients. The PAC may add useful data in some overdose situations such as [1] assessment of left heart filling pressures when persistent pulmonary edema is present (e.g., hydrocarbon aspiration or adult respiratory distress syndrome) and [2] assessment of myocardial contractility (cardiac output and stroke volume) to determine the severity of myocardial depression and efficacy of therapy (e.g., calcium channel antagonist overdose). Although several case reports describe the use of a PAC in a calcium channel antagonist overdose [101, 108, 153–155], no studies address either the indications for placement or whether the information obtained from the pulmonary catheter changes the outcome in these patients.

There are risks associated with the insertion of a PAC. Common complications include pulmonary artery injury, valvular injury, endocarditis, heparin-induced thrombocytopenia, catheter or balloon embolization, pulmonary infarction, ventricular arrhythmia, and cardiac perforation [156]. In addition, PACs are technically

challenging to use [157–159]. Due to these limitations, there is a shift toward using less invasive and less challenging methods to monitor hemodynamic function [160] (Level III recommendation). As with PACs, these methods are not investigated in poisoned patients. Arterial pulse contour and pulse power analyses are less invasive alternatives to measure cardiac output [161]. Lithium dilution cardiac output (LiDCO PlusTM) uses these principles to estimate cardiac output [162]. Isotonic lithium chloride is injected via a central or peripheral venous route to calculate cardiac output. The lithium doses used are too small to cause any pharmacologic effect. LiDCO was found to be an effective alternative to PAC [163]. Other non-invasive devices that provide similar information include the PiCCO PlusTM and FloTracTM [164]. These devices use different calibration schemes to model the transfer of arterial pulse pressure to stroke volume. Doppler cardiac monitoring devices are alternatives that require neither arterial or venous cannulation [165]. Esophageal or transthoracic Doppler probes measure flow in the descending aorta and estimate cardiac output. These products suffer from technical limitations, as probe position is crucial to obtaining accurate measurements. In addition, basic central venous catheters can measure central venous pressure and SvO₂ with fewer complications than PACs.

Bedside sonography is an even less invasive alternative used to guide resuscitation. The rapid ultrasound in shock (RUSH) protocol can determine the etiology of cardiovascular collapse [62]. The RUSH protocol is an easily learned technique that involves assessing the heart (“the pump”), inferior vena cava (IVC) and internal jugular (IJ) (“the tank”), and arterial vessels such as the aorta (“the pipes”). RUSH can exclude cardiac tamponade, decreased cardiac contractility, hypovolemia, hemothorax, pneumothorax, and aortic aneurysm as the cause of shock. In addition, a standard focused assessment in trauma (FAST) exam is included to exclude hemoperitoneum as the etiology of the hypotension.

Sonography also provides information about left and right ventricular function, central venous pressure, and fluid responsiveness. In addition to excluding tamponade, cardiac sonography is

useful to evaluate both left and right ventricular function. Ventricles with good contractility will have a large change in volume between systole and diastole [166]. Motion of the anterior leaflet of the mitral valve also assess contractility. In the parasternal long axis, the anterior leaflet should nearly touch the septum in diastole if the ventricle is contracting normally. The normal ratio of the left to right ventricle is 1:0.6. Right ventricular dilation indicates increased pressure within the pulmonary vascular circuit, such as with a large pulmonary embolism or pulmonary hypertension, as the cause of hypotension [167, 168]. Inferior vena cava measurement is used to determine volume status and fluid responsiveness; it also acts as a surrogate for central venous pressure (CVP) [169]. The size and change in size of the IVC during inspiration accurately estimates CVP [170]. An IVC with a diameter less than 2.1 cm that collapses more than 50% correlates with normal CVP and volume responsiveness [171]. Serial measurements as opposed to a single measurement during the resuscitation are recommended to more accurately guide volume management [62]. The IJ can be used instead of the IVC [172]. Common carotid velocity time integral (VTi) with passive leg raise (PLR) also measures volume responsiveness. In PLR, a patient's legs are raised 45° while their upper body is kept horizontal, and the patient is assessed for changes in stroke volume or cardiac output [173]. Carotid artery flow velocity is measured with Doppler sonography to determine VTi. The common carotid artery's diameter is measured using Doppler to evaluate the flow [174]. Increases in VTi following PLR accurately predict volume responsiveness [175]. A 20% increase in VTi following PLR predicted volume responsiveness with a sensitivity of 94% and specificity of 86% [175]. This topic is further discussed in ► Chap. 14, "The Assessment and Management of Hypotension and Shock in the Poisoned Patient."

Sedation and Paralysis

When a patient is intubated and is in the ICU, sedation and analgesia are important to minimize discomfort. Some patients have vivid recall of

events that occurred in the ICU [176]. These events (discomfort, being in unfamiliar surroundings, invasive procedures performed by total strangers) are terrifying because the patient's consciousness is clouded from illness and partial sedation; in fact, inadequate sedation and analgesia can lead to post-traumatic stress disorder (PTSD) [177]. At the same time, excess sedation causes delirium, with some literature associating it with distress and PTSD [178, 179]. Worse yet is being paralyzed without adequate sedation or analgesia and being unable to communicate [180]. For overdose patients, the patient's underlying emotional instability may complicate management further (see ► Chap. 6, "Psychiatric Issues in the Critically Poisoned Patient").

Patients intubated due to their toxicologic exposure may be agitated and require sedation. Until recently, this was typically achieved via benzodiazepine administration (continuous infusion or intermittent, around-the-clock dosing) or by continuous propofol infusion, with greater than 80% of critically ill patients sedated with one of these agents [181]. The α -2 agonist dexmedetomidine is now being used either in addition to these agents or replacement of them (Level I recommendation). A multicenter, randomized, double-blind trial compared midazolam or propofol to dexmedetomidine in intubated patients and was found to be non-inferior in maintaining light to moderate sedation [182]. It did reduce the duration of intubation compared to midazolam ($p = 0.03$) but not propofol ($P = .24$). As dexmedetomidine is unlikely to cause respiratory depression, it can be used with noninvasive positive pressure ventilation [183]. However, this is controversial and one randomized, double-blind, placebo-controlled pilot study did not find that it improved tolerance to noninvasive ventilation [184]. Recent trials in patients with sedative-hypnotic withdrawal indicate that dexmedetomidine may be a useful adjunct; however, more studies are required to determine its safety and efficacy in this population [185, 186]. Dexmedetomidine was administered to 22 poisoned patients who were intubated in an ICU [187]. Most patients (77%) required additional sedatives or analgesics and five patients

suffered adverse events. Further studies are needed to determine the role of dexmedetomidine in poisoned patients.

Continuous infusion provides a constant serum drug concentration and decreases the chance of the patient awakening or becoming agitated [188, 189]. Continuous sedative infusions of benzodiazepines and propofol, compared with intermittent dosing, prolong ventilator time and ICU time, however, as a result of overmedication [190]. For poisoned patients, as for all ICU patients, analgesia is as important as sedation. Neither benzodiazepines nor propofol provide analgesia, which is problematic as the endotracheal tube is a significant source of pain and discomfort [191]. Dexmedetomidine may provide analgesia in addition to sedation via receptors in the spinal cord [187]. Narcotic analgesics, such as fentanyl and morphine, may decrease the pain and discomfort patients experience from intubation, having invasive devices in place, and an inability to move. Combining narcotics with sedative-hypnotics decreases the amount of sedative-hypnotics required for comfort [192]. Simultaneous administration of opioids and propofol may cause hypotension, especially if large doses are used. Caution is warranted in patients who are poisoned by cardiovascular agents and therefore prone to hypotension.

Lorazepam and propofol are commonly used sedatives in the ICU. Continuous infusion of midazolam, compared with continuous infusion of propofol or lorazepam, lengthens time until the patient is awake and extubated after sedation has been stopped [193–195]. In critically ill patients, the midazolam half-life and volume of distribution are increased [196]. The half-life is prolonged further in renal failure [197]. In addition, sedation with midazolam may lead to higher rates of PTSD compared to other sedatives [179]. Benzodiazepines can also cause delirium [198], which is an independent predictor of death and prolonged ICU length of stay [199]. Infusions of propofol for greater than 48 h are associated with propofol infusion syndrome (PRIS) [200]. PRIS is a syndrome of refractory bradycardia, metabolic acidosis, rhabdomyolysis, hyperlipidemia, and fatty liver; patients can even

develop myocardial failure or cardiovascular collapse. Patients sedated with dexmedetomidine and other α -2 agonists develop bradycardia and hypotension. Haloperidol is also used as an adjunctive therapy for sedation. Independent of which sedative agents are used, daily interruption of sedation to assess the patient's neurologic status shortens the duration of mechanical ventilation and ICU length of stay [201].

Analgesia-based sedation or analgosedation is another option in the intubated patient [198, 202] (Level II-2 recommendation). Here, the primary objective is to control pain with an analgesic and only administer a sedative-hypnotic if necessary [203]. Analgosedation was demonstrated to be as effective as a sedative-hypnotic approach while reducing the dose of administered sedatives. Patients treated with analgosedation were able to be weaned from the ventilator sooner and had shorter ICU lengths of stay compared to standard management [204]. Just as with sedative-hypnotics, dosing of analgesics may need to be adjusted due to altered pharmacokinetics in critically ill patients [205].

In postoperative patients, the use of topical anesthetics to the pharyngeal, laryngeal, and tracheal mucosa statistically decreased the amount of sedation required [206]. As patients begin to regain consciousness and experience discomfort from the endotracheal tube, the use of topical anesthetics may relieve discomfort without requiring consciousness-altering medications. This may also be true of nonsurgical, intubated patients. Topical anesthetics must be administered judiciously because overzealous administration may cause significant methemoglobinemia and local anesthetic systemic toxicity.

In the overdose patient, sedation is often less problematic as patients are often intubated due to taking central nervous system depressants and can usually be extubated within 24 h. Overdose patients with depressed mental status may not require sedation if they were intubated due to their depressed mental status and inability to protect their airway. When the clinical effects of the overdose begin to resolve, either further sedation or ventilator liberation must be performed. In these situations if additional sedation is required,

intermittent administration of fentanyl (or another short acting opioid) or an infusion of dexmedetomidine, combined with the use of topical anesthetics, may be the best choice (Level III recommendation). This combination avoids oversedation and allows for continuous assessment of the patient's mental status and other clinical signs and symptoms indicating that the patient is ready to be liberated from the ventilator. Benzodiazepines, propofol, or dexmedetomidine can always be added to opioids if further sedation is required. Many patients, especially those presenting following polypharmacy overdoses, are delirious or have a fluctuating level of alertness. They may benefit from small amounts of sedation, until enough of the substances have worn off for them to be extubated. In general if the patient is sufficiently awake and can protect their airway, rapid ventilator liberation and extubation is appropriate. For otherwise healthy overdose patients, extubation usually can be accomplished safely without a "wean from the ventilator."

Neuromuscular blocking agents (NMBAs) should be used in only two circumstances in the poisoned patient: [1] in patients who, despite adequate sedation, still have a high oxygen demand owing to the work of respiratory muscles and [2] in patients poisoned with xenobiotics such as strychnine (Level III recommendation). Normally, about 5% of oxygen consumed by the body (VO_2) is used by the respiratory muscles. In critically ill patients, this can be 25% or greater [207]. Although therapeutic paralysis decreases VO_2 , it has been shown that administering an NMBA to patients who are adequately sedated does not decrease VO_2 further [208]. Critically ill patients who have received NMBAs may develop persistent muscular weakness after discontinuation of the NMBA [209–211], even after short-term or intermittent NMBA administration [212]. The effect may last for weeks or months. The presence of renal dysfunction allows for the accumulation of active metabolites from some NMBAs (e.g., vecuronium). Addition of steroids (e.g., in patients with either upper airway obstruction or lower airway bronchospasm) increases the risk and severity of prolonged muscular weakness

[209]. NMBAs should be administered only if the patient can benefit from decreasing VO_2 requirements. NMBAs should never be used to control an agitated patient. The cause should be investigated and treated (e.g., increase sedation or analgesia, change the vent settings), which will likely improve the agitation without the need for NMBAs. Paralysis should not be used as a punitive intervention or to absolve the physician from the need to sedate an agitated patient. A poisoned patient seldom requires the use of an NMBA, unless adult respiratory distress syndrome, sepsis, hyperthermia from severe neuromuscular agitation (e.g., severe serotonin syndrome), or a toxicant such as strychnine is part of the clinical picture.

Ventilator Liberation

When the patient begins to show improvement, the issue of ventilator liberation arises. *Liberation* is a more desirable term, and a better mind set, than *weaning* for discontinuing ventilatory support. Weaning implies a gradual withdrawal of ventilator support, and most poisoned patients do not need to be "weaned" from the ventilator. Of 456 patients evaluated for participation in a trial designed to compare ventilator modes during liberation, 347 (76%) were liberated after an initial 2-h, spontaneous-breathing T-piece trial [213]. These findings have been confirmed in other studies [214]. As many overdose patients are intubated due to agitation or decreased mental status, most can be extubated as soon as their mental status improves and do not require a formal wean (Level III recommendation).

The conditions that led to the patient's being intubated and ventilated need to be resolved. In the case of overdoses, most respiratory failure is type II (hypercapnic) from decreased mental status and respiratory drive. When the patient regains his or her respiratory drive and the ability to protect their airway, ventilator liberation should proceed rapidly. If type I (hypoxemic) respiratory failure was involved, adequate oxygenation on 40% FiO_2 and PEEP of less than 5 cm H_2O should be present before liberation is attempted [215]. In

type IV (shock) respiratory failure, the patient should be hemodynamically stable and metabolic abnormalities corrected. If type II (hypercapnic) respiratory failure from respiratory muscle weakness has complicated the clinical course, liberation may require a more thoughtful approach, which is outlined subsequently.

Indices previously used to determine whether respiratory muscle strength was adequate for liberation have included a negative inspiratory force less than -20 cm H₂O, respiratory rate less than 35 breaths/min, V_T greater than 5 mL/kg, V_E less than 10 L, and forced vital capacity greater than 10 mL/kg [216, 217]. All of these parameters are moderately sensitive but poorly specific [218]. Their utility in the overdose or poisoned patient population has not been evaluated.

The rapid shallow breathing index (RSBI) was developed to assist in the bedside assessment of patients who are potentially ready for ventilator liberation [219]. The RSBI quantifies what we intuitively know about patients' breathing patterns: patients who take deep breaths at a slow rate are ready for ventilator liberation, whereas patients breathing rapidly are unlikely to be successfully liberated. The RSBI is performed while the patient is spontaneously breathing for 1 min without any ventilator assistance. The respiratory rate is divided by the spontaneous V_T in liters. Patients with an RSBI greater than 105 are at risk of failing ventilator liberation. The RSBI is highly sensitive (0.97) and moderately specific (0.64) in medical ICU patients [219]. Further studies have shown a sensitivity and specificity equal to the original study when the RSBI is performed after 30 min of spontaneous breathing [220]. The RSBI is valid in surgical patients, as well [221]. Analysis of patients failing liberation with RSBI less than 100 found that most fail due to new problems unrelated to the original process that caused them to be intubated, such as new-onset congestive heart failure, upper airway obstruction, and aspiration [222]. The utility of the RSBI in overdose or poisoned patients has not been studied.

Questions may arise about which ventilator mode to use during ventilator liberation. As mentioned previously, the SIMV mode can increase the work of breathing. For the general ICU

population, once-daily trials of spontaneous breathing lead to extubation three times faster than SIMV and two times faster than pressure support ventilation [214]. It is not known whether this applies to toxicology patients.

If there is concern that the patient may not be ready for ventilator liberation, a simple five-step procedure can be followed:[218].

1. Ensure all underlying abnormalities that led to intubation are corrected.
2. Assess the RSBI. If the RSBI is greater than 105, therapy to decrease respiratory workload and increase respiratory muscle strength should be employed.
3. For patients with an RSBI less than 105, perform a 2-h spontaneous breathing trial (SBT). This is accomplished by placing the patient on a T-piece or on continuous positive airway pressure with minimal or no pressure support.
4. Evaluate the patient during the SBT. Failure of a SBT manifests as diaphoresis, tachypnea, desaturation, tachycardia, hypotension, or arrhythmias.
5. If the patient tolerates a 2-h SBT, he or she is ready to be liberated from the ventilator.

Ventilator liberation does not imply that extubation should be performed, just as an inability to protect the airway does not imply respiratory failure. Other factors need to be considered, especially in cases of upper airway injury such as following a caustic injury. Bedside assessment of airway adequacy may be determined by endotracheal tube "cuff leak." The cuff-leak test can be performed in one of two ways. The first is to disconnect the patient from the ventilator, deflate the endotracheal tube's cuff while it is still in place, occlude the end of the tube, and listen for air passing around the tube. The second is to leave the endotracheal tube connected to the ventilator, deflate the cuff, and measure the difference between the V_T delivered by the ventilator and the V_T returned to the ventilator. If there is a leak, the delivered V_T will be greater than the returned V_T . Prospective evaluation of 72 patients with upper airway obstructions using the first method led to successful extubation in 89% of patients

with a cuff leak [223]. Using the second method, patients who did not develop stridor on extubation averaged 360 mL cuff leak with average V_T of 650 mL [224]. Patients who did develop stridor, given the same average V_T , had cuff leaks of only 180 mL. These data, along with direct visualization of the upper airway, can assist the clinician in deciding whether patients with upper airway obstruction are ready for extubation.

Ancillary Issues in the Intensive Care Unit Management of Poisoned Patients

Certain management issues need to be addressed in all patients who enter the ICU. Any patient who is critically ill, is intubated, or has a PAC requires a daily chest x-ray. New findings are discovered in 15–45% of daily chest x-rays [225–228], 8% had findings of “major” clinical significance (e.g., pneumothorax, improperly positioned endotracheal tube), and 42% of these findings (3.3% of total) were not suspected previously from bedside assessment [229].

Critically ill, poisoned patients are at increased risk of GI bleeding. Of ICU patients, 75% have endoscopic evidence of gastric mucosal injury by 18 h after admission, with 5% of patients developing overt bleeding [230]. GI bleeding prophylaxis should be started on admission to the ICU and can be achieved best through the use of histamine₂-receptor antagonists or proton-pump inhibitors [231] (Level I recommendation).

Poisoned ICU patients are at risk for venous thromboembolic disease if they have a prolonged course requiring them to remain in bed. Approximately 33% of all ICU patients develop ultrasonographically detectable DVTs despite receiving prophylaxis. Meta-analyses show that the use of heparin or pneumatic compression stockings decreases the incidence of DVT by at least 50% [232]. DVT prophylaxis should be initiated with unfractionated heparin, low-molecular-weight heparin, or compression devices as soon as the patient is admitted to the ICU if a prolonged stay is anticipated (Level I recommendation).

The goal of nutritional support is to meet the patient’s nutritional needs without overfeeding. This may be difficult because critically ill patients can be catabolic with a negative nitrogen balance. Exact caloric requirements can be determined through indirect calorimetry (“metabolic cart”). Overfeeding should be avoided because excess carbohydrates can lead to increased carbon dioxide production, which leads to higher minute ventilation needs. The increased ventilation needed to blow off the excess carbon dioxide may prevent liberation from the ventilator. Enteral feedings, which help maintain integrity of the gut’s mucosal barrier, are preferred over the parenteral route. If a prolonged stay is anticipated, feedings optimally should be initiated within the first 24 h after admission. If ventilator liberation is anticipated within the first 24–48 h, as is typical of many poisoned patients, enteral feedings are not necessary.

Gastrointestinal Decontamination

Gastrointestinal decontamination, once a mainstay in the management of the intoxicated patient, has greatly fallen out of favor. It is generally relegated to patients that present very early (less than an hour after their ingestion) or for those patients who took a very large or dangerous overdose, where an antidote does not exist (e.g., verapamil) (Level III recommendation). While once common, the administration of syrup of ipecac or the performance of gastric lavage should not be done, and administration of even single-dose activated charcoal (AC) is now rare. Intuitively GI decontamination should decrease absorption of many xenobiotics. However, its use is not associated with improved patient-centered outcomes (e.g., mortality, length of stay) [233–235].

If GI decontamination is attempted, it should be done as early as possible in the patient’s treatment to have any chance of being beneficial. If it is preformed, this should occur in the emergency department, shortly after the patient arrives; the patient is very unlikely to benefit from decontamination started in a delayed fashion, such as in the ICU. However, patients who ingest sustained

release preparations, have heavy metals in their GI tract, or are body packers may benefit from whole bowel irrigation (WBI) (Level II-3 recommendation). In addition if the patient has a bezoar, GI decontamination may be beneficial.

Activated charcoal is produced in a two-step process, starting with pyrolysis of various carbonaceous materials. It is then treated at high temperatures with oxidizing agents such as steam or carbon dioxide that “activate” it and increase its adsorptive capacity. Activated charcoal adsorbs many xenobiotics but does not adsorb metals or strongly ionized substances. In addition, it should not be administered to patients with caustic injuries, as it will obscure landmarks during the endoscopy. Serious adverse events include chemical pneumonitis following aspiration, peritonitis if it is administered to a patient with perforation of their GI tract, and pseudo-obstruction in patients with an ileus or obstruction. In their most recent position statement, the American Academy of Clinical Toxicology (AACT) and the European Association of Poisons Centres and Clinical Toxicologists (EAPCCT) compared 122 studies in human volunteers [235]. There was a large amount of variability in the types of xenobiotics ingested, the amount of xenobiotic ingested, and the amount of charcoal administered. While absorption was decreased when AC was administered within 30 min, the mean reduction was only 16% when administered two hours after the ingestion. Studies of AC in patients with ingestions are difficult to interpret as they include patients receiving multiple types of decontamination in addition to AC or have serious methodological or statistical flaws. Merigian et al. investigated the outcome of 451 asymptomatic patients who received either 50 g of AC or no treatment and did not find a statistically significant change in clinical outcomes between the groups [236]. Buckley et al. conducted a retrospective, non-randomized study on 981 consecutive patients admitted following acetaminophen overdoses [237]. Activated charcoal was administered in 36% of patients and 39% of patients were not decontaminated. Patients that received AC were significantly less likely (odds ratio 0.36) to have acetaminophen concentrations in the probable or high-risk portion

of the nomogram. However, the mean time to presentation in the no treatment group was 385 min versus 135 min in the treatment group. If AC is administered, it should be dosed at 1 g/kg if the dose is unknown or in a 10:1 ratio of AC to xenobiotic if known; most adults receive approximately 100 g of AC. Administration of a cathartic with AC is controversial. The current position of the AACT does not support the routine use of activated charcoal, even though benefit cannot be excluded if AC is administered more than one hour after the ingestion [235] (Level I recommendation). AC may be considered in patients that present within one hour of a toxic ingestion, which would still exclude its use in patients after they are admitted to the ICU. Multidose activated charcoal (MDAC) is used to enhance the elimination of various xenobiotics. Multidose activated charcoal may benefit patients at risk from delayed absorption due to ingesting delayed release products or if they ingested xenobiotics that cause pylorospasm or bezoar formation, such as salicylates [238]. In these scenarios, MDAC prevents absorption of the xenobiotic. Patients that ingest xenobiotics that undergo enteroenteric or enterohepatic circulation may also benefit from MDAC. In enterohepatic circulation, absorbed substances are secreted into the bile and then into the small intestine before being reabsorbed. In enteroenteric circulation, absorbed substances are secreted into the intestine before being reabsorbed. By administering MDAC, charcoal can adsorb xenobiotics that are secreted into the intestine before being reabsorbed, thereby enhancing elimination. In these scenarios, the xenobiotic has already been absorbed so MDAC is not being used for the purpose of decontamination but as an adjunct to increase elimination by preventing reabsorption. Both animal and human data demonstrate that MDAC increases xenobiotic elimination [239–241]. However, MDAC has not been shown to decrease morbidity or mortality [242]. MDAC is generally administered at a dose of ½ gram/kg following the initial standard dose of charcoal. In pediatric patients, the dose may need to be decreased. Cathartics should not be administered with MDAC as repeated dosing causes electrolyte disturbances and dehydration.

Multidose activated charcoal may be administered every four hours. However, the timing of MDAC administration is patient and provider specific. Multidose activated charcoal should be withheld in patients with altered mental status and an unprotected airway, GI tract obstruction or disruption, and an ileus. Currently, the AACT/EAPCCT only recommends the administration of MDAC in patients who have ingested life-threatening amounts of either carbamazepine, dapsone, phenobarbital, quinine, or theophylline [243] (Level II-3 recommendation). Xenobiotics whose elimination may be increased by MDAC are discussed in their respective chapters.

Over the last 10–20 years, the use of gastric lavage has drastically decreased due to concerns that complications from the procedure outweigh any benefit. Given the real risks associated with it, the AACT and EAPCCT do not recommend the use of gastric lavage [234]; in situations where a clinician believes lavage may be appropriate, either AC or supportive care should be considered instead (Level II-2 recommendation).

Whole bowel irrigation prevents absorption by attempting to enhance the flow of xenobiotics through the gut. In order to achieve this, a nasogastric or orogastric tube must be placed. Large amounts, approximately 1–2 l/h, of osmotically balanced polyethylene glycol solution (PEG) are administered until the patient has at least two clear, liquid stools. Unlike other forms of GI decontamination, WBI may be started or continued in the ICU. Patients that have ingested sustained release preparations may be candidates for WBI in order to prevent delayed absorption; this is also why WBI may be considered in patients with bezoars. If patients are suspected of ingesting metals and have radiopaque foreign bodies on imaging, WBI may prevent absorption, as AC will not adsorb metal. Lastly, body packers are traditionally treated with WBI. Body packers internally smuggle large amounts of packets in order to smuggle narcotics. Should a packet leak, each one has a potentially lethal amount of drug in it. There are multiple retrospective case studies and cohorts in body packers that received WBI [244–246]. Interpretation of some of the literature is limited due to patients either refusing to drink

the PEG solution or WBI not recorded as being completed. While efficacy of WBI is difficult to interpret, no adverse events were reported in these studies; however, aspiration has been reported with WBI [247, 248]. In body packers, WBI should be initiated in order to remove the packets as soon as possible, given the life-threatening risk associated with even a single packet leaking. Contraindications include patients with an ileus or obstruction or an injury to their GI tract. While there are multiple reports suggesting that WBI can assist with the passage of tablets or packets, there is no evidence to support that WBI improves clinical outcomes [249]. The AACT and EAPCCT do not routinely recommend the use of WBI, but it can be considered in select situations (Level II-2 recommendation).

Antidotes

Most poisoned patients can be treated with standard supportive care, as detailed earlier. In certain instances specific therapy or antidotes are required. Specific therapies are described in subsequent chapters dealing with specific substances. Properties of specific antidotes are described in chapters at the end of the book. Some antidotes that may be administered in the ICU are listed in Table 8.

Table 8 Examples of antidotes that may be used in the ICU

Toxin/poison	Antidotes
α-2 agonist (clonidine, guanfacine, guanabenz, tizanidine, methyl dopa)	Naloxone
Acetaminophen	N-acetylcysteine
Anticholinergic agents	Physostigmine
Benzodiazepines	Flumazenil (with caution)
β-Adrenergic blocking agents	Glucagon Lipid emulsion therapy
Black widow envenomation	Latrodectus antivenin
Botulism	Botulin antitoxin
Calcium channel antagonists	Calcium Glucagon

(continued)

Table 8 (continued)

Toxin/poison	Antidotes
	Insulin and glucose
	Methylene blue (amlodipine)
	Lipid emulsion therapy
Carbamate insecticides	Atropine
Carbon monoxide	Oxygen or hyperbaric oxygen
Cyanide	Amyl and sodium nitrites
	Hydroxocobalamin
	Sodium thiosulfate
Digoxin/digitoxin	Antidigoxin antibodies
Dystonic reactions	Diphenhydramine
	Benzotropine
Ethylene glycol	Ethanol
	Fomepizole
	Thiamine and pyridoxine
Fluoride	Calcium salts
Heparin	Protamine
Heavy metals	Dimercaprol (BAL)
	Penicillamine
	Dimercaptosuccinic acid (DMSA)
	Calcium ethylenediaminetetraacetic acid (EDTA)
	Dimercaptopropanesulfonic acid (DMPS)
Isoniazid/hydrazines (<i>Gyromitra</i>)	Pyridoxine
Iron	Deferoxamine
Methanol	Ethanol
	Fomepizole
	Folate or folinic acid
Methemoglobinemia	Methylene blue
Methotrexate, trimethoprim, pyrimethamine	Folinic acid
	Glucarpidase
New oral anticoagulants	Prothrombin complex concentrates (Xa inhibitors)
Opiates	Hemodialysis (dabigatran)
	Idarucizumab (dabigatran)
	Naloxone (methylnaltrexone only reverses opioid induced constipation)
Oral hypoglycemics	Glucose infusion
	Octreotide
Organophosphate insecticides	Atropine
	Pralidoxime/obidoxime
Rattlesnake envenomation	<i>Crotalidae antivenin</i>

(continued)

Table 8 (continued)

Toxin/poison	Antidotes
Scorpion envenomation	Anascorp [®] antivenin
Sodium channel blockade (TCAs, type I antiarrhythmics)	Sodium bicarbonate
	Hypertonic saline
Warfarin	Vitamin K
	Fresh frozen plasma

Subspecialty Care

In the United States, medical toxicology is a recognized subspecialty by the American Board of Medical Specialties. There are currently 500–600 board-certified practicing medical toxicologists in the United States. These individuals have the greatest experience in the care of critically poisoned patients. When available, on-site or telemedical consultation is recommended. In some areas highly specialized regional poison treatment centers have been established to which critically poisoned patients might be transferred.

Acknowledgment Edward M. Bottei and Donna L. Seger contributed a prior version of this chapter in the previous edition of this text.

Cardiopulmonary deterioration is a final common pathway of many life-threatening conditions, including those induced by toxins. Despite advances in resuscitation and critical care, severe pulmonary and cardiac failures are associated with a high risk of organ failure and death. Extracorporeal membrane oxygenation (ECMO) is a growing rescue modality for patients with acute reversible life-threatening cardiopulmonary conditions.

ECMO Principles

Extracorporeal membrane oxygenation (ECMO), also referred to as extracorporeal life support (ECLS), leverages the technological advances of intraoperative cardiopulmonary bypass to provide temporary, miniaturized, closed-circuit support in the intensive care unit. In most instances, ECMO is a rescue technique for severe but reversible heart or lung failure that is predicted to be imminently lethal despite conventional support. Prime ECMO candidates have acute, severe, but reversible cardiac or respiratory failure. In this context, ECMO provides physiologic support for anticipated native organ recovery. Underlying advanced, chronic organ dysfunction and age greater than 65 years are common relative contraindications based on decreased capacity to survive life-threatening illness in this group. Extracorporeal membrane oxygenation may also be used to bridge patients with irreversible cardiac or respiratory disease to a more durable form of support such as ventricular assist device (VAD) or heart or lung transplant.

The ECMO system consists of intravascular cannulae, an extracorporeal circuit with oxygenator that provides gas exchange, and a pump to drive blood flow (Table 1, Fig. 1). Cannulation configuration dictates the mode of support. Venovenous (VV) ECMO cannulation provides gas exchange for lung failure, while veno-arterial (VA) ECMO configuration supports both cardiac and pulmonary functions. Interposition of a hemodialysis limb in the ECMO circuit enables concurrent renal replacement therapy. Altered volume of distribution, drug adsorption to

Return cannula

ECMO components, and underlying organ dysfunction impact the pharmacokinetics of many therapeutic (and toxic) agents and highlight the need for clinical and laboratory monitoring [1].

Systemic anticoagulation with vigilant monitoring is generally required to prevent patient and circuit thrombosis and embolization. Heparinized circuits and high flow rates can abrogate the need for anticoagulation in some circumstances where systemic bleeding risk is high. Large vessel instrumentation and systemic anticoagulation underlie the significant risk of clinically important hemorrhage with this modality. Life-threatening hemorrhage occurs in up to 10 % of cases with intracranial hemorrhage impacting 4–6 % [2–4]. Other recognized complications are listed in Table 2. Peripheral percutaneous cannulation (i.e., jugular vein and femoral vein and artery) is preferred to limit infectious and bleeding complications compared to central thorax instrumentation. However, technical issues may prioritize central cannulation, especially in patients with an open chest or with severe lung dysfunction. Carotid artery cannulation also remains a viable option for neonates and children.

Extracorporeal membrane oxygenation is a unique high-intensity resource (Fig. 1) that is not available in all facilities. Early transfer to a capable center should be considered for patients whose clinical trajectory predicts possible need for this modality [5, 6]. Patient retrieval by ECMO teams, including cannulation prior to transport, is an option supported by some centers [7]. Dedicated ECMO clinicians manage patients on this modality. Extracorporeal membrane oxygenation-trained specialists or perfusionists provide continuous bedside management in concert with the intensive care unit staff. Specialty

Surgical
Local and regional bleeding from large-bore vascular catheters
Vascular injury (transection and dissection)
Nidus for deep venous thrombosis formation
Vascular occlusion (central nervous system and distal limb ischemia)
Systemic
Bleeding at distant site due to anticoagulation (intracranial, gastrointestinal, pulmonary, mediastinal)
Thrombocytopenia
Hemolysis
Infection

ECMO physicians typically manage patient selection and ECMO support.

Anticipated meaningful recovery needs to be considered for ECMO candidacy. Advanced multi-organ failure, severe chronic organ dysfunction, and age greater than 65 years are common relative contraindications based on decreased capacity to survive severe life-threatening illness in patients with these characteristics. We advise multi-professional conference to clarify ECMO goals and patient eligibility prior to cannulation,

when time allows. A time limit of ECMO support should similarly be discussed with the care team and patient family based on expectation for recovery [8].

Veno-Venous ECMO (VV ECMO)

Veno-venous ECMO cannulation drains blood from the central circulation and reintroduces the blood to the proximal venous circulation following extracorporeal gas exchange via the artificial membrane oxygenator. In addition to providing critical blood oxygenation and carbon dioxide removal, reliance on extracorporeal gas exchange enables attenuation of ventilator support to avoid both ventilator-induced lung injury and adverse hemodynamic effects of aggressive ventilator support [9]. Because oxygenated blood is returned to the venous circulation in this configuration, systemic oxygen delivery is determined by native cardiac performance. Other than removing the untoward effects of mechanical ventilation, VV ECMO does not provide material cardiovascular support.

Clinical conditions requiring rescue VV ECMO are typically associated with severe bilateral lung disease. Severe hypoxemia due to acute respiratory distress syndrome (ARDS) stemming from a variety of insults and refractory

Table 3 Example clinical criteria for VV ECMO consideration

Criteria of lung failure
Refractory hypoxemia
PaO ₂ /FiO ₂ < 60 with FiO ₂ ≥ 80 % for > 3 h despite optimized mechanical ventilation
PaO ₂ /FiO ₂ < 80 with FiO ₂ ≥ 80 % for > 6 h despite optimized mechanical ventilation
PaO ₂ /FiO ₂ < 100 and PaCO ₂ ≥ 100 for > 1 h
Oxygen index [(FiO ₂ × mean airway pressure × 100)/PaO ₂] > 30–35
Refractory hypercapnia
pH < 7.2 with PaCO ₂ ≥ 80 for > 6 h despite optimized mechanical ventilation
Ventilator induced barotrauma or severe air leak syndrome
Relative contraindications to VV ECMO support
Acute respiratory failure with high mechanical ventilation setting > 7 days
Moderate to severe underlying cardiopulmonary disease
Additional severe organ dysfunction
Life expectancy due to premorbid disease < 6 months
Age > 65 years

hypercarbia in status asthmaticus are conditions where ECMO is a cost-effective treatment that improves survival [10]. Severe unilateral lung disease such as pneumonia, pulmonary contusion, and bronchopleural fistula can also result in life-threatening failure of pulmonary gas exchange. Individual center patient selection criteria for ECMO vary but are generally based on criteria predicting greater than 50–70 % mortality. Examples of candidate criteria for rescue VV ECMO are provided in Table 3.

Veno-Arterial ECMO (VA ECMO)

The return limb of veno-arterial ECMO distributes to a central systemic artery such that VA ECMO provides both gas exchange and artificial hemodynamic support similar to traditional cardiopulmonary bypass. Refractory cardiogenic shock is the clinical situation that prompts consideration for rescue VA ECMO. Typical acute conditions are myocardial infarction, refractory

Table 4 Example clinical criteria for VA ECMO consideration

Criteria of refractory cardiogenic shock
Sustained CI ≤ 2.2 with evidence of malperfusion despite optimization by volume resuscitation, inotropes, and vasopressors
Consideration of any alternative form of extracorporeal support (intra-aortic balloon pump, temporary ventricular assist device)
Minimal and reversible secondary organ dysfunction
Absolute contraindications
Known intracranial bleeding
Irrecoverable myocardial insult and not a candidate for transplant or ventricular assist device
Relative contraindications
Bleeding risk from anticoagulation
Age > 65 years
Life expectancy due to premorbid disease < 6 months
Chronic organ dysfunction that limits meaningful recovery (end-stage liver disease)
Peripheral vascular disease that limits vascular access

dysrhythmias, myocarditis, massive pulmonary embolus, cardiotoxic overdose, postcardiotomy shock, decompensated chronic heart failure, sepsis-induced cardiomyopathy, and deep hypothermia. Cardiac arrest represents the extreme case of shock and is an emerging focus of ECMO in the form of extracorporeal cardiopulmonary resuscitation. Extracorporeal cardiopulmonary resuscitation (ECPR) appears feasible in settings experienced with this modality but outcome evidence is purely observational to date [11, 12]. Examples of candidate criteria for rescue VA ECMO are provided in Table 4.

Unique and important clinical considerations for VA ECMO support include adequate peripheral arterial access to allow appropriate-sized arterial cannulation, heightened need for systemic anticoagulation to avoid intracardiac and arterial thromboembolism, and risk of differential regional hypoxemia with peripheral cannulation in patients with severe lung failure. Prioritized patient selection issues focus on early identification and ECMO implementation prior to irrecoverable organ failure and a distilled plan for durable cardiovascular support. Native heart recovery is a reasonable

expectation in some conditions (ECMO as a bridge to recovery). However, ECMO frequently bridges patients to a point where native function is incompletely restored. As such, longitudinal mechanical cardiac support options such as ventricular assist device (VAD), total artificial heart, or cardiac transplant candidacy should be discussed prior to ECMO cannulation, when time allows.

ECMO in Xenobiotic-Induced Cardiopulmonary Failure

Although not a novel therapeutic modality, the use of veno-venous or veno-arterial ECMO has recently gained more interest and momentum for treating toxin-induced pulmonary or combined cardiopulmonary failure. At one time, extracorporeal life support was rarely used to treat toxins due to the availability, timeliness, and invasive nature of instituting cardiopulmonary bypass. However, the advent of percutaneous vascular access rather than open chest techniques in the 1980s rendered ECLS more amenable for use outside of the operating room to aid in the treatment of severe xenobiotic intoxication. ECMO has since been used to treat a wide variety of pharmaceutical, chemical, environmental, and natural toxins. Over 170 ECMO cases involving greater than 50 xenobiotics appear in the English language medical literature (Tables 5 and 6).

The evidence to weigh the true value of ECMO for toxins is challenging. There are few experimental animal models (level III evidence), and the published clinical experience is comprised of case reports and a limited number of case series (level III evidence). Thus the level of evidence is low and there is significant publication bias especially due to the large proportion of single case reports. In reality however, the relatively low prevalence of toxin-induced cardiopulmonary failure precludes any large-scale definitive, prospective human study such as a randomized clinical trial. With these evidentiary limitations in mind, the majority of cases where ECMO was employed for refractory shock or outright cardiac arrest are associated with good outcomes.

Experimental Evidence

Three preclinical studies evaluated the efficacy of ECMO for toxin-induced shock (level III evidence). Each study utilized the veno-arterial ECMO technique that proved superior to other experimental treatments. One study involved lidocaine toxicity and two investigated cyclic antidepressants. In the lidocaine study, canines were poisoned with a large intravenous bolus (30 mg/kg) until animals developed cardiovascular collapse and then received either standard pharmacological resuscitation or ECMO for 90 min. All animals receiving ECMO treatment survived compared with only 25 % for those receiving standard treatment [89]. Extracorporeal life support increased survival (6/6 vs. 1/6 animals) and decreased vasopressor requirements in canines with desipramine-induced cardiac arrest versus standard advance cardiac life support drugs plus mechanical cardiopulmonary resuscitation (CPR) [90]. Swine infused with amitriptyline to induce severe shock were treated for 90–120 min with ECMO or standard pharmacological therapy. As in the first two studies, there was impressive survival in the ECMO group (100 vs. 10 %) at 6 h [91].

Although all three preclinical studies provide positive evidence for ECMO use in drug-induced cardiogenic shock and cardiac arrest, there are critical limitations to translating the impressive results in these models to the human experience. Foremost, there was no delay to ECMO in the models. Animals were instrumented prior to poisoning and treatment was immediately instituted upon reaching toxicity. This model does not replicate the human scenario where treatment delays to ECLS are expected. Secondly, these studies were conducted over relatively short durations (hours) and did not assess for long-term clinical outcomes such as neurological outcome or complications due to therapy itself. Lastly, the trials evaluated one local anesthetic and two cyclic antidepressants. No other common cardiovascular xenobiotics have been studied in this manner.

Table 5 Case report summaries

Xenobiotic ^a	Age	VV vs. VA ECMO	Duration	Other treatments C,G,HD,HDI,L,TH	Complications	Survival	Neurological outcome
Acebutolol [13]	27 years	VA	12 h	G,HD,V	DVT	Yes	No comment

Clinical Reports

Early ECMO for humans began primarily with toxin-induced lung injury and ARDS in children, owing to the prior experience with ECMO for neonatal lung dysfunction. Survival from hydrocarbon pneumonitis varied in initial papers: 0 % and 63 % [46, 47]. The application of ECMO has since broadened to a variety of other xenobiotics and ages following the early experience. The majority of published cases now involve direct cardiovascular toxins historically associated with high morbidity and mortality such as β -adrenergic blocking drugs, calcium channel antagonists, and sodium channel antagonist drugs. Extracorporeal membrane oxygenation was employed in cases of acute respiratory distress syndrome and cardiopulmonary failure due to other drug classes including analgesics, antimalarials, newer antidepressants, chemotherapeutics, and other miscellaneous agents. Environmental and chemical exposures have been managed with ECMO as well (Tables 5 and 6).

While both veno-venous and veno-arterial ECMO are utilized, the vast majority of toxic cases were managed with the veno-arterial modality. The duration of ECMO therapy in cases of direct myocardial toxins varies in the modern series, averaging between 35 h and 7 days [80, 82–87]. The shortest ECMO use (1.5 h) was described during intraoperative resuscitation of bupivacaine toxicity [22]. Extracorporeal membrane oxygenation requirement is generally longer in the treatment of primary and secondary pulmonary injury [47]. The longest duration (35 days) involved a complicated case of marijuana/phencyclidine lung injury [52].

Clinical outcome has improved since the initial publications: likely a reflection of wider availability and better technology. Observational series published after 2000 demonstrate survival rates averaging 68 % and ranging from 25 % to 86 % [80–88]. Interestingly, the majority of these cases experienced cardiac arrest before or at the time ECMO was initiated. Extracorporeal membrane oxygenation was often delayed during resuscitation with CPR averaging 79–120 min in three series [80, 82, 83]. Cardiopulmonary resuscitation duration ranged from 45 to 180 min [82, 83].

Although details regarding quality of life associated with successful ECMO are not always provided or described in a systematic fashion, long-term outcome and function are generally good. Of 20 survivors in three combined series, 16 had cerebral performance category (CPC) score 1 and four survivors had CPC score 2, indicating normal and near-normal function, respectively [81–83]. In another series, all survivors, including xenobiotic-related cases, were described as alive and well without neurological sequelae at follow-up (mean 17 months) [84].

Direct-Acting Cardioactive Agents

The majority of individual cases and published series involve direct-acting cardiac toxins including antidysrhythmics [14, 15, 62, 66], β -adrenergic blockers [13, 18, 20, 21, 43, 44, 55, 63, 64, 78], calcium channel antagonists [17, 18, 35, 36, 73–78], digoxin [34], local anesthetics [22, 51, 53], and both sodium channel agonists and antagonists [18, 22, 24, 25, 28, 33, 38–44, 50, 68–70]. In ECMO series containing both toxic and nontoxic causes of cardiopulmonary failure, outcomes are significantly higher for patients with a toxic etiology. In three series totaling 120 patients, 22/37 (59 %) with toxin-induced cardiopulmonary failure survived versus 13/83 (16 %) that were due to medical causes of failure (coronary ischemia, dysrhythmia, cardiomyopathy) [81, 82, 88]. The greater survival was attributed to the temporary nature of xenobiotic intoxication. Coronary artery disease produces myocardial injury that may or may not be reversible. Toxins on the other hand typically interfere with receptor or ion channel activity and this dysfunction can be reversed with specific or supportive therapy. Thus, drug-induced cardiovascular collapse may be an optimal targeted use for ECMO.

Direct Pulmonary Toxins

Extracorporeal membrane oxygenation may be used to treat primary and secondary toxin-related lung injury. The toxic lung insults may occur due

to a variety of mechanisms. Ideally, veno-venous ECMO may be used to restore adequate oxygen delivery to tissues until pulmonary tissue recovers. However, veno-arterial ECMO was utilized in the majority of the cases and series where there was a toxic lung injury. Extracorporeal membrane oxygenation requirement for pulmonary toxicity is generally longer than that of direct myocardial toxins: up to 35 days in one recent report of ARDS after smoking marijuana and phencyclidine that was dipped in embalming fluid [52]. This is likely due to the presence of tissue injury following pulmonary toxin exposure rather than reversible receptor dysfunction in the case of myocardial toxins.

Childhood hydrocarbon exposure is common as a result of accidental ingestion. The earliest experiences with ECMO were derived from treating hydrocarbon-induced lung injury and associated complications in children. Hydrocarbons interfere with surfactant that leads to altered compliance and also initiate tissue inflammation. Both processes decrease gas exchange and result in inadequate ventilation and hypoxia. Although most patients experience mild to moderate pneumonitis, some patients may progress to fulminant respiratory failure. Veno-venous or veno-arterial ECMO was applied to 24 children with hydrocarbon pneumonitis refractory to supportive measures [46, 47, 48]. Extracorporeal membrane oxygenation duration in these patients averaged 13 days (range 6–26 days). Outcome was generally good: 19 of 24 patients survived.

Extracorporeal membrane oxygenation has been used in three cases of severe pulmonary toxicity following the ingestion of the bipyridyl herbicide, paraquat [58–60]. Paraquat may injure mucous membranes, kidneys, muscle, and lungs. Of these targeted organs, lung injury is primarily responsible for mortality. Paraquat has a unique mechanism that involves accumulation of the herbicide in lung tissue and generation of free radicals that selectively injure type I pneumocytes. The clinical expression of the injury is progressive pulmonary fibrosis that may be rapid and irreversible. Reported mortality is high: 30–80 % depending on the dose [92, 93]. Survivors may suffer long-term restrictive pulmonary

dysfunction [93, 94]. Although a variety of pharmacological therapies have been used and studied, there are no proven antidotes. With few alternatives, patients with fulminant pulmonary failure have undergone lung transplant [58–60, 95–97]. Initial transplant attempts failed [60, 95, 96]. These early failures may have been due to challenging surgery and immunosuppression for the time period. One other contributing factor may have been persistent paraquat in the tissues that injured the transplanted lung. Paraquat has been detected in the lung and muscle 6–59 days after exposure [59, 96, 97]. In some cases, it was present in the tissue, but absent in serum [97].

In one report, veno-venous ECMO was used on two separate occasions until transplant [60]. Extracorporeal membrane oxygenation supported the patient for 8 days prior to transplant. However, the transplant failed with evidence of paraquat toxicity. Extracorporeal membrane oxygenation was reinstituted for 19 days until a second transplant took place. The patient died of myopathy and surgical complications 3 months after the second transplant. Because of the potential to injure the transplanted tissue, another group advocates delayed transplant as long as possible until paraquat is cleared using ECMO as bridge [58]. In their case, veno-venous followed by veno-arterial ECMO sustained the patient for 20 days. Unfortunately, the patient died awaiting a donor. In the third case, a patient was started on ECMO on hospital day 44 and then maintained on veno-venous ECMO for 12 days until successfully transplanted 56 days post-ingestion [59]. Interestingly, the explanted lung still contained measurable paraquat. Although the persistence of paraquat is variable and optimal timing of transplant after exposure is undefined, these cases demonstrate that ECMO can successfully serve as a bridge to transplant for a sustained period of time. Paraquat-induced pulmonary injury is discussed in greater detail in the paraquat and diquat chapter.

Extracorporeal membrane oxygenation was used in severe pulmonary injury due to other xenobiotics including amiodarone [16], carbon monoxide/smoke inhalation [26, 87], nitric acid [56], radiocontrast [67], tainted marijuana/phencyclidine

[52], and zinc chloride [79]. It was successful for the cases involving amiodarone, carbon monoxide/smoke inhalation, marijuana/phencyclidine, radio-contrast, and zinc chloride.

Anti-inflammatory Drugs

Colchicine is an antimitotic drug used to treat gout, pericarditis, and Familial Mediterranean fever. It has a low therapeutic index and, following therapeutic misadventure or large ingestion, may cause multisystem organ failure that includes cardiogenic shock and dysrhythmias. Mortality is high in cases when there is multi-organ involvement. Extracorporeal membrane oxygenation was used to treat three intentional colchicine overdoses and an accidental ingestion of *Colchicum autumnale* [29–31, 82]. Cardiogenic shock developed in all cases. Two received 10 days of ECMO support and survived with normal cardiac and neurological function [29, 30]. The third patient experienced extraordinarily rapid collapse in the first few hours after overdose and received less than 24 h of ECMO support, and care was withdrawn on hospital day 2 after massive bleeding [31]. Extracorporeal membrane oxygenation duration was not specified in the fourth case [82].

A massive, intentional ibuprofen ingestion with severe hypotension and acidosis received 4 days of ECMO and survived [49].

Antimalarials

Acute ingestion of the antimalarial/immunosuppressive drugs, chloroquine and hydroxychloroquine has resulted in refractory cardiac dysrhythmias and shock due to myocardial sodium channel inhibition and potassium channel dysfunction. One might surmise that ECMO is a viable treatment option for severe chloroquine and hydroxychloroquine toxicity based on their underlying cardiac mechanism and good outcomes following ECMO use in other direct-acting cardiac agents. However, ECMO use was unsuccessful in three cases [27, 82].

Chemotherapeutic Agents

Cardiogenic shock and dysrhythmias are well-recognized complications during chemotherapy with cyclophosphamide, a nitrogen mustard, and 5-fluorouracil, a pyrimidine analogue. Extracorporeal membrane oxygenation support for 6 days allowed myocardial function to recover from 5-fluorouracil toxicity and the patient survived [45]. In a case of cyclophosphamide-induced cardiogenic shock with pericardial effusion and cardiac arrest, 5 days of veno-arterial ECMO permitted myocardial recovery [32]. However, the clinical course was complicated by intracranial bleeding and care was eventually withdrawn.

Newer Antidepressants

Bupropion is a cathinone derivative with antidepressant activity due to dopamine, serotonin, and norepinephrine reuptake inhibition. Toxicity affects the central nervous system (agitation, seizures) and cardiovascular system (ventricular dysrhythmias, initial hypertension, hypotension). In rare cases, cardiogenic shock may occur. In three cases of severe bupropion toxicity, healthcare providers incorporated ECMO into resuscitation. One case resulted from an accidental ingestion that developed persistent hypoxia and hypotension [23]. Two other cases resulted in cardiogenic shock after intentional ingestion [24]. All three patients survived without evidence of neurological injury. One patient had residual leg weakness related to cannula placement and required rehabilitation [24].

Opioid Analgesics

Opioid overdose may infrequently result in severe ARDS and, even more rarely, combined cardiopulmonary failure. Veno-venous and veno-arterial ECMO was used in five such cases that included dextropropoxyphene [82], fentanyl [37], methadone (two cases) [54], and tramadol [71, 72]. All of the patients survived with good outcome except for the dextropropoxyphene ingestion.

Pesticides

In addition to paraquat, previously highlighted in the direct pulmonary toxin section, ECMO has been used to treat aluminum phosphide and organophosphorus compound exposures. Aluminum phosphide is a common fumigant that may cause multisystem injury due to inhibition of enzymes, inhibition of oxidative phosphorylation, and depletion of antioxidant compounds. The acute respiratory distress syndrome and cardiovascular shock may occur. When cardiogenic shock is present, mortality approaches 70 % [86]. In one pediatric exposure that resulted from lawn fumigation with aluminum phosphide, ECMO was started but care was withdrawn due to severe neurological injury [61]. In a case series involving intentional ingestion, ECMO appeared beneficial [86]. Seven patients received ECMO for an average of 74 h (range 43–144 h) to treat acidemia and cardiogenic shock. Five of seven survived and were reported to do well at 2–8 months of follow-up.

Following intentional ingestion of a commercial mixture of fenitrothion/malathion insecticide complicated by environmental hypothermia, a patient underwent 39 h of ECMO (with aortic balloon pump) for refractory hypotension and rewarming. The patient survived [57].

Plants

Numerous plants contain cardioactive compounds that may result in toxicity after intentional ingestion of extracts, teas, or the plants themselves. The yew (*Taxus* species) is a coniferous shrub that contains taxine, a cardiotoxic alkaloid. Ingestion of the leaves may result in ventricular dysrhythmias due to interference with sodium and calcium channel activity. Three patients that intentionally ingested yew survived ventricular dysrhythmias, ventricular failure, and cardiac arrest following management that included veno-arterial ECMO [68–70]. One case of accidental *Colchicum autumnale* ingestion was treated with ECMO as discussed in the anti-inflammatory section [29]. Although there are no current published cases of ECMO use for plant-related digitalis

toxicity, it could potentially be used to treat severe cardiac glycoside exposure based on anecdotal experience with pharmaceutical digoxin overdose [34]. Several species such as foxglove, oleander, and squill contain cardioactive glycosides that can result in typical digitalis cardiotoxicity following ingestion and, in severe toxicity that is refractory to immunotherapy, might benefit from ECLS.

Miscellaneous Xenobiotics

ECMO has been undertaken following exposures to arsenic [19], carbamazepine [25], diphenhydramine [87], metformin [87], methanol [87], and quetiapine [65].

Bridge to Organ Donation

Extracorporeal membrane oxygenation served as a bridge to organ harvesting after intentional ingestion of flecainide and betaxolol [44]. In this case, veno-arterial ECMO facilitated critical organ recovery in a neurologically devastated patient. The heart, kidneys, and liver were successfully transplanted and demonstrated normal function in each recipient at 45 months of follow-up.

Complications

Complications due to the ECMO procedure are common and can be life threatening. Of 67 case reports (73 total cases) that were reviewed for this chapter, 27 report one or more complications (see Tables 5 and 7). In ten cases, authors specifically state that there were none [15, 17, 27, 33, 41, 48, 50, 53, 54, 63]. The remainder do not discuss the presence or absence of complications. The complications observed following ECMO in these cases and several case series are similar to those associated with nontoxic-related ECMO experience with bleeding being the most common [21, 25, 29, 31, 32, 35, 36, 38, 42, 43, 45–49, 51, 78, 82–85]. The bleeding complication rate in the nine published case series (103 total patients)

ranged from 12 % to 71 % [47, 81–86]. Bleeding may be local or systemic. Although percutaneous vascular access has widened the availability of ECMO, the large-bore vascular catheters are the most common source of bleeding complications. Bleeding may occur at the percutaneous site and, less frequently, into adjacent tissues such as the mediastinum or retroperitoneum. Anticoagulation is necessary during ECMO and may lead to additional bleeding sites including the brain, peritoneum, lung, myocardium, and gastrointestinal tract. Large-volume transfusion and/or surgery is often required to correct the bleeding [25, 31, 35, 49, 81, 82, 84–86]. One additional downside to

percutaneous access is vascular occlusive events due to placement of large-bore catheters needed to maintain adequate blood flow. Limb ischemia is common, sometimes leading to compartment syndrome and necessitating fasciotomy and surgical revascularization [21, 36, 56, 78, 81, 83]. The frequency of limb ischemia and related complications may be decreased when ECMO access is modified to include placement of a second vascular catheter that maintains distal limb flow [80]. The placement of large-bore vascular catheters has caused extremity nerve palsies [22, 24, 54]. Large vessel thrombotic events may occur as well even in the face of anticoagulation [13, 25, 37, 39, 83]. Hemolysis is reported [20, 47]. Coagulopathy occurs [25, 38, 39, 48]. Lastly, mechanical events related to the pumps, oxygenator, heater, and lines are reported [22, 47, 76].

Compatibility

Extracorporeal membrane oxygenation is never used in isolation for resuscitating xenobiotic pulmonary or cardiopulmonary failure; all of the toxic-related cases also received pharmacological agents (antidotes, antidysrhythmics, vasopressors, and supportive drugs) or other technology-based treatments (cardiac pacing, dialysis, therapeutic hypothermia).

Pharmacokinetic Considerations

Currently, there is very limited experience and understanding (primarily in the neonatal ECMO literature) with how pharmacological and technological treatments impact each other. Concomitant use of specific toxicological pharmacotherapy during ECMO includes calcium [17, 18, 20, 22, 35, 36, 53, 73, 75, 78], chelation [19], digoxin Fab [34, 70], glucagon [13, 17, 18, 20, 21, 35, 36, 44, 49, 55, 64, 75, 78], high-dose insulin [17, 18, 36, 55, 73, 78], methylene blue [17], and oxime [57]. None of these reports address kinetics, complications, effectiveness, or toxicity of these antidotes related to ECMO.

Several factors that are often encountered with critically ill patients or related to the ECMO procedure itself may impact antidote pharmacokinetics. For example, patients with cardiopulmonary failure frequently have multi-organ dysfunction, especially liver and renal dysfunction, with subsequent impaired drug metabolism and elimination. ECMO itself affects drug behavior. The pump, circuitry tubing, oxygenator, gas exchange unit, and filters create additional volume that is not accounted for in weight-based dosing, resulting in xenobiotic dilution and apparent increased drug volume of distribution [98–100]. This is likely more pronounced in children than in adults. Extracorporeal membrane oxygenation circuitry sequesters many xenobiotics, resulting in xenobiotic loss as demonstrated in *ex vivo* studies of pediatric [101–105] and adult patients [106]. In these reports, ECMO circuits used polyvinylchloride and silicone tubing with crystalloid and/or blood as circuit priming agents. Each study demonstrated some degree of drug loss to the circuit including anticonvulsants (fosphenytoin, phenytoin), analgesics (fentanyl, morphine), anticoagulants (heparin), sedatives (diazepam, lorazepam, midazolam, propofol), and vasopressors (dopamine, epinephrine). Clinically, this translates to challenges in anticoagulation and sedation drug dosing during ECMO. Heparin requirements are greater for neonates while on ECMO [107]. Sedative drug dose requirements are also increased in order to achieve adequate patient comfort and safety during ECMO [108]. Although not directly studied in ECMO, insulin is also known to bind to intravenous tubing and glass, possibly affecting high-dose insulin [109, 110]. No preclinical or clinical studies address sequestration of antidotes used to resuscitate drug-induced cardiopulmonary failure. Thus, the compatibility or impact of ECMO on antidote pharmacokinetics and dynamics remains largely unknown in this evolving technology.

Intravenous fat emulsion infusion (“lipid rescue”) is sometimes used in an attempt to reverse severe drug-induced cardiotoxicity, possibly by serving as a lipid sink that removes lipophilic compounds from target tissues [111, 112]. Additionally,

critically ill patients often require prolonged hospitalization, so lipid emulsions may be given for nutritional support while undergoing ECMO. These concentrated fat emulsions have potential to complicate or interfere with ECMO. Rescue lipids are known to interfere with routine laboratory analysis and may result in fat deposition in the lungs [113]. In two *in vitro* studies and a clinical series, investigators inspected ECMO circuits during and after 24 h of lipid infusion and found fat deposition in areas of low flow, broken stop cocks, and blood clotting within the oxygenator despite anticoagulation [114–116]. To decrease the interference with ECMO, neonatologists recommend infusing nutritional lipid therapy separately into patients and not directly into the ECMO circuit [114, 115]. Lipids and ECLS were used in twelve cases involving seven adults and five children [17, 23, 24, 27, 36, 40, 41, 43, 48, 55, 73, 76]. Twelve involved acute lipid rescue therapy prior to or during ECMO and one child received fat emulsion for nutritional support while undergoing ECMO [48]. In four cases, authors specifically commented (in the manuscript or via personal communication with this chapter authors) that lipid infusion was uncomplicated [17, 24, 27, 55]. Minor complications occurred in two instances: lab interference [27] and need for multiple ECMO filter changes [76]. Although there are potential complications with intravenous lipid infusion during ECMO, the current literature suggests that lipid rescue may be lifesaving for lipophilic cardiovascular toxins, and the limited downside of infused lipid should not prevent its use in appropriate circumstances when ECMO is also under consideration.

Concomitant Use of Other Technological Treatments

Extracorporeal drug elimination measures such as high-flux hemodialysis, continuous veno-venous hemofiltration, continuous renal replacement therapy, charcoal hemoperfusion, and plasmapheresis can be added to the ECMO circuit [13, 18–21, 24, 30, 43, 57, 62, 65, 66, 71, 73, 76–78, 86]. The primary indication for dialysis in most of these

cases was acute renal injury and metabolic acidosis. There were no unexpected complications due to simultaneous use of ECMO and the various dialysis techniques. In several cases, ECMO stabilized hemodynamics allowing for effective extracorporeal drug clearance [13, 20, 73].

Transvenous pacemaker was used in thirteen cases [18, 33, 36, 38, 39, 41, 42, 64, 66, 68, 74, 76, 78] and successfully increased heart rate in four [18, 33, 36, 76] and transiently in two patients [66, 74]. Failure of pacemaker capture in the remaining cases was most likely related to the drug insult rather than the ECMO procedure.

Therapeutic hypothermia involves cooling post-cardiac arrest patients to target temperature of 32–34 °C to protect the brain from ischemic reperfusion phenomenon. Two recent series discuss the experience with therapeutic hypothermia for xenobiotic-induced cardiac arrest [117, 118]. As many toxin-related ECMO cases experienced cardiac arrest prior to starting ECMO, it is not surprising that therapeutic hypothermia and ECMO have begun to intersect. Both treatments were used in four adults [14, 18, 55, 70] and in one child [40]. None of these reports describe complications due to simultaneous use of these two therapies. However, cooling to target temperature impacts drug behavior and may further complicate pharmacokinetics of resuscitation when used alongside with ECLS. The limited pharmacokinetic understanding with therapeutic hypothermia suggests both similar and opposing effects on drug kinetics compared to ECMO. Unlike ECMO, cooling generally decreases the volume of distribution due to hemoconcentration [119]. Cooling also prolongs drug clearance due to decreased enzymatic activity and decreased cardiac output [119]. This may result in drug accumulation and exaggerated effect and toxicity or, if the xenobiotic requires activation through metabolism, loss of effect. However, there are no pharmacokinetic studies for patients undergoing both ECMO and therapeutic hypothermia. From a practical standpoint, ECMO may facilitate more controlled cooling, maintenance of target temperature, and rewarming due to in-line cooling/heating rather than relying on cold intravenous fluid administration and external cooling devices.

Complication and Compatibility Summary

Resuscitation of xenobiotic-induced cardiopulmonary failure continues to evolve. Both standard and emerging pharmacological and technological treatments rendered for drug-induced cardiopulmonary failure appear to be safe and compatible with ECMO. However, evidenced-based understanding of the effects with combined resuscitation modalities on efficacy, pharmacokinetics, and complications is on the upslope of the experiential learning curve. As the frequency of ECMO and other emerging treatments increases in cardiopulmonary resuscitation, vigilance for optimal use of combined modalities as well as for unexpected complications and untoward effects is necessary.

Suggested Use of ECMO for Xenobiotic Toxicity

Extracorporeal membrane oxygenation is ideally considered for severe xenobiotic-induced pulmonary or combined cardiopulmonary failure that is refractory to maximal antidotal, conventional supportive pharmacological or technological modalities and meets suggested parameters outlined in Tables 3 and 4. In this regard, the insult should be recoverable following the addition of ECMO support. The potential exception to this general principle of recoverability is toxin-induced injury where ECMO may serve as a bridge to transplant, such as in the case of paraquat. Contraindications are limited and the only absolute contraindication known is intracranial bleeding. Relative contraindications include severe hypoxic brain injury, irrecoverable insult, poor clinical severity score, and comorbidities such as severe bleeding disorder (that prevents anticoagulation) or peripheral vascular disease (that might impede vascular access). Other relative contraindications include comorbidities with shortened life expectancy such as advanced age, cirrhosis, and advanced malignancy.

The challenge of when to initiate ECMO is twofold. First, healthcare providers must perform a benefit–risk assessment and determine if

there is a potential benefit from this relatively high-risk procedure. Most severe cardiopulmonary insults can be successfully managed with lower-risk therapies. The second challenge lies in deciding when standard therapies have reached their maximal effect and are now failing in a manner that affords sufficient time to institute ECMO before the pulmonary or myocardial insult becomes irreversible. Intuitively, the faster the restoration of critical organ perfusion, the better the chances of good long-term outcome; hence ECMO should be started as soon as possible. That being said, many of the cases involving toxins experienced cardiac arrest prior to ECMO and survived with good neurological performance scores despite delays to ECMO and prolonged CPR.

Conclusions

ECMO provides temporary support for lung and combined lung and heart failure. It has a history grounded in treating neonates with lung dysfunction, growing use in adults with cardiopulmonary failure, and more recent interest for severe toxic insult due to a variety of xenobiotics including drugs, natural toxins, and chemicals. In experienced centers, ECMO may be a lifesaving rescue option for severe xenobiotic toxicity when standard of care measures fail. As its use increases for toxins, scientific scrutiny is needed regarding efficacy, safety, optimal duration, and impact on concomitant treatments.

The care of patients by protocol following cardiac arrest has been associated with significant improvement in survival to hospital discharge in recent years, with studies citing >50% survival in patients suffering pulseless ventricular tachycardia or ventricular fibrillation cardiac arrests [1–3]. Survival improvements have been suggested but are less clear following cardiac arrest with an initial rhythm of asystole or pulseless electrical activity [4]. Management of cardiac arrest as a result of poisoning as well as subsequent postarrest care present unique challenges to providers. Concepts applied to postarrest care in all patients, including aggressive temperature management, maintenance of end-organ perfusion, oxygenation and ventilation, and correction of metabolic derangements, are likely to be transferrable to a poisoned patient population. However, the etiology and necessary interventions required to manage the arrest and postarrest sequelae vary greatly among poisoned patients and are distinct from patients suffering cardiac arrest as a result of underlying cardiopulmonary disease. At the same time, underlying disease must continue to be considered as a contributor and complicating factor of acute poisoning. Depending upon the inciting agent, management may include specific antidotal therapy, serum and/or urinary alkalinization, and/or rescue therapy such as extracorporeal membrane oxygenation (ECMO) in addition to standard advanced cardiac life support. Treatment

modalities geared toward specific agents will be addressed in corresponding chapters.

Few data exist regarding standardized care after toxin-induced cardiac arrest. Review of 85 out of hospital cardiac arrests felt to be related to drug overdose, primarily from recreational drugs, indicated several key differences in this group compared to patients suffering “natural” cardiac arrest. Patients in the overdose group were found to be younger, have fewer comorbidities, presented more frequently with non-shockable rhythms (e.g., asystole or pulseless electrical activity), and had worse baseline neurologic function. Nevertheless, despite the seemingly poorer presenting characteristics, survival was similar to the non-overdose group and neurologic recovery was superior [5]. The conclusions in this study were reproduced on subsequent examinations of larger populations in two separate databases of cardiac arrest victims [6, 7]. These studies did not evaluate in-hospital cardiac arrest and was geared primarily to evaluating cardiac arrest secondary to drugs of abuse. Cardiac arrests related to cardiovascular agents and other antidysrhythmics such as sodium channel blockers likely carry a very different prognosis.

In this chapter, general principles of post-cardiac arrest care will be discussed with special consideration given to unique aspects of the poisoned patient including challenges in the neurologic evaluation of postarrest patients, the influence of temperature regulation on drug disposition, and ECMO. Potential complications of lipid emulsion therapy, sometimes used during attempts to resuscitate poisoned patients, will also be discussed.

Initial Post-cardiac Arrest Clinical Assessment

After resuscitation and return of spontaneous circulation (ROSC), initial evaluation using a standardized examination and scoring system may be used to assist in management decisions as well as prognosis. While several scoring systems have been suggested, we recommend the Pittsburgh Post-Cardiac Arrest Category (PCAC) score

Table 1 Clinical components used to determine the Pittsburgh Cardiac Arrest Category. Vasopressor doses are in $\mu\text{g/kg/min}$. *FOUR* Full Outline of UnResponsiveness, *SOFA* Sequential Organ Failure Assessment, *Dop* dopamine, *Dob* dobutamine, *Epi* epinephrine, *Nor* norepinephrine

<i>FOUR score: motor component</i>
4 points: follows commands
3 points: localizes to pain
2 points: flexion response to pain
1 points: extensor response to pain
0 points: no response to pain OR generalized myoclonic status
<i>FOUR score: brainstem component</i>
4 points: pupil AND corneal reflexes present
3 points: unilateral fixed/dilated pupil
2 points: pupil OR corneal reflexes absent
1 points: pupil AND corneal reflexes absent
0 points: pupil AND corneal AND cough reflexes absent
<i>SOFA score: cardiovascular component</i>
4 points: $\text{Dop} > 15$ OR $\text{Epi} > 0.1$ OR $\text{Nor} > 0.1$
3 points: $\text{Dop} > 5$ OR $\text{Epi} \leq 0.1$ OR $\text{Nor} \leq 0.1$
2 points: $\text{Dop} \leq 5$ or Dob (any dose)
1 points: $\text{MAP} < 70$ mmHg
<i>SOFA score: respiratory component</i>
4 points: $\text{PaO}_2/\text{FiO}_2 < 100$ AND on ventilator
3 points: $\text{PaO}_2/\text{FiO}_2 < 200$ AND on ventilator
2 points: $\text{PaO}_2/\text{FiO}_2 < 300$
1 points: $\text{PaO}_2/\text{FiO}_2 < 400$

because it is based on objective factors obtainable through bedside examination of the patient rather than reliance on historical factors. The PCAC is a validated postarrest assessment tool using brainstem and motor components of the Full Outline of UnResponsiveness (FOUR) score of initial neurologic function as well as cardiovascular and respiratory components of the Sequential Organ Failure Assessment score of cardiopulmonary dysfunction [8, 9] (Tables 1 and 2).

In the typical postarrest population, this scoring system places a patient on a four-tiered prognostic stratification system, which predicts both survival to hospital discharge as well as the likelihood of good neurological outcome (Fig. 1).

Tools such as the PCAC have significantly advanced our ability to predict clinical outcome and course following out of hospital cardiac arrest with ROSC. However, their use is predicated on the absence of sedative agents for neurologic evaluation. In the case of the poisoned patient, the

Table 2 PCAC category based upon FOUR and SOFA scores including a description of the corresponding clinical examination

Category	Clinical description	FOUR score Motor + brainstem	SOFA score Cardiovascular + respiratory
I	Awake, follows commands	8	Any
II	Moderate coma with preservation of some brainstem reflexes	4–7	≤3
III	Moderate coma with preservation of some brainstem reflexes and severe cardiopulmonary failure	4–7	≥4
IV	Deep coma with loss of most or all brainstem reflexes	≤3	Any

**Fig. 1** Survival and good neurologic outcome based upon PCAC category at the time of initial evaluation. Good neurologic outcome is defined as discharge to home or acute rehabilitation facility (Data from Ref. [8])

presence of a central nervous system sedative agent such as an opioid or GABA-A agonist is common. Significant neurologic toxicity can mimic brain death thereby placing a poisoned patient in PCAC IV and a less than 10% survival rate [10]. Additionally, the initial cardiovascular evaluation assumes that dysfunction represents cardiac injury and hypoperfusion. However, in the case of cardiovascular toxicants such as sodium channel blockers, beta-blockers, calcium channel blockers, and cardiac glycosides, persistent cardiovascular insufficiency following ROSC is often the result of ongoing toxicity, which, though potentially severe and difficult to reverse, would be expected to be transient and self-limited. These observations likely account for the

disparity identified in the review of drug-induced out of hospital cardiac arrest victims in whom survival and neurologic outcome were better than would have otherwise been anticipated [5]. While prognostic scoring systems have significantly improved our ability to predict outcomes and make informed treatment decisions in postarrest patients, the limitations of neurologic and cardiovascular evaluation make accurate prediction of outcome following toxin-induced cardiac arrest difficult requiring further investigation to identify accurate prognostic indicators in this population.

Post-cardiac Arrest Management

Resuscitation approaches in the poisoned patient are largely driven by the specific agent and toxic mechanism. However, in cases that are not related to poisoning, initial evaluation must begin with consideration of myocardial ischemia and early cardiac catheterization [11, 12]. Evaluation of potential underlying contributing coronary artery disease in appropriate patients must also remain part of the evaluation of the presumed poisoned patient. Electrocardiographic abnormalities assumed to be related to acute toxicity including sodium channel blockade and heart block may also represent primary myocardial ischemia necessitating intervention. Bedside echocardiography may help determine volume and pump status. In addition to specific toxin-based interventions, optimization of post-cardiac arrest care with the goal of minimizing ongoing

neurologic and cellular injury while maximizing recovery potential involves employing a standardized protocol requiring significant resources and institutional support [13].

Ventilator Management

In addition to treating the underlying toxicity, standard postarrest care consists of a multifaceted approach to maintain end-organ perfusion, particularly cerebral perfusion. In order to meet cellular demands, adequate oxygenation must first be addressed. The vast majority of patients who have suffered cardiac arrest will require mechanical ventilation. Obvious exceptions would be patients discovered shortly after easily treated causes of arrest, most notably opioid intoxication with naloxone reversal.

As in all critically ill patients, assurance of appropriate airway security is the first priority. Once a secure airway has been verified, mechanical ventilation goals are of normoxia and normal to slightly elevated PaCO_2 levels. Persistent hypoxemia with subsequent diminished cellular oxygen delivery following cardiac arrest should be avoided. Persistently elevated partial pressure of oxygen may also be harmful. A meta-analysis of 14 observational studies of patients with ROSC after cardiac arrest indicated that, while there was no difference in neurologic outcome, there was increased mortality in patients with hyperoxia, $\text{PaO}_2 > 300$ mmHg [14]. In the poisoned patient, there may be exceptions to this recommendation. For example, treatment of patients suffering cardiac arrest as a result of a cellular asphyxiant (e.g., azide, carbon monoxide, cyanide, hydrogen sulfide) theoretically calls for delivery of 100% oxygen, regardless of oxygen saturation, with the goal of maximizing mitochondrial oxygen supply and, in some cases, displacing the offending agent. In the case of carbon monoxide specifically, high flow oxygen is recommended and hyperbaric oxygen is debated [15]. This controversy is discussed in detail in ► Chap. 96, “Carbon Monoxide”. The potential risks versus benefits of hyperoxygenation in this patient population are not clear. However, if there is no indication for hyperoxia,

titrating FiO_2 to maintain a PaO_2 of approximately 100 mmHg is reasonable to ensure adequate cellular oxygen delivery without potentially worsening overall outcome. An alternative end point that may be used to assess adequacy of oxygen delivery is central venous oxygen saturation of greater than 70%, based upon extrapolation from sepsis data [16]. However, this marker may not accurately reflect cellular oxygen delivery and extraction in patients suffering mitochondrial toxicity or hemoglobinopathies.

Despite diminished baroreceptor function, chemoreceptor response to hypocarbica remains intact in the postarrest brain [17]. As a result, hyperventilation can lead to cerebral arterial vasoconstriction and impaired cerebral perfusion [18]. Hyperventilation may also lead to diminished venous return. Decreased cardiac output secondary to falling preload may further exacerbate hypoperfusion injury [19]. For these reasons, the American Heart Association guidelines recommended that PaCO_2 be maintained at approximately 40–45 mmHg [20]. In cases of severe metabolic acidosis that is refractory to treatment, hyperventilation may be necessary to raise pH. Salicylate poisoning is especially sensitive to changes in pH, with even a relatively small decrease contributing to an increase in the nonionized fraction and worsened toxicity. Unless mandated by the toxicant or severity of metabolic acidosis, hyperventilation for therapeutic purposes should be avoided in postarrest patients in order to prevent cerebral hypoperfusion (Grade III recommendation).

Hemodynamic Management

The primary goal of hemodynamic management at any time, including following cardiac arrest, is to maintain adequate perfusion of tissue to avoid further injury. Following cardiac arrest, the brain is at particular risk of secondary injury and is extremely sensitive to even brief periods of hypoperfusion [21]. A number of physiologic phenomena account for hypotension, hypoperfusion, and enhanced brain injury. Reperfusion injury following a period of reduced

oxygen delivery, as is seen in the postarrest patient, causes a distributive shock similar in pathophysiology to septic or systemic inflammatory response states. Moreover, myocardial dysfunction as a result of a period of diminished or absent coronary flow results in reduced cardiac output [22]. Finally, loss of cerebral autoregulatory mechanisms impairs the brain's ability to adapt to fluctuating cerebral perfusion pressure leading to ongoing secondary neurologic injury in addition to the initial anoxic insult [23, 24].

Secondary injury is prevented or minimized by closely monitoring and maintaining organ perfusion. Evaluation of cellular perfusion entails evaluation and interpretation of a number of physiologic end points. No single data point is sufficient to predict satisfaction of cellular oxygen demands. Blood pressure is often used as the primary surrogate for perfusion. While not a perfect reflection of cellular oxygen delivery, it correlates closely with perfusion and alterations in blood pressure, especially decreases in mean arterial pressure (MAP), is associated with worsened outcomes following cardiac arrest [25]. Therefore, we recommend arterial catheter placement in patients requiring vasopressor therapy to ensure accurate and continuous monitoring of blood pressure. Due to observed loss of cerebrovascular autoregulation, studies have suggested the need for maintaining a higher MAP in postarrest patients as compared to patients suffering shock without cardiac arrest [24]. Specialists in post-cardiac arrest care at our institution recommend a goal MAP of 80 mmHg in non-poisoned patients when reasonably attainable. The American Heart Association Guidelines published in 2010 concede that human studies have not determined an ideal MAP and recommend that MAP remains greater than 65 mmHg [20]. Maintenance of MAP will frequently require the use of vasoconstricting and/or inotropic agents. The potential benefits of neuroprotective strategies must be weighed against the practical cardiovascular risks of accentuating cardiac oxygen demand and strain, particularly while managing cardiovascular intoxication. Care can also be negatively impacted if excessive vasoconstriction causes poor perfusion of other organs such as the

kidneys and gut leading to progressive kidney injury or mesenteric ischemia [26]. Other indicators of cellular perfusion include urine output, central venous oxygen saturation, serum bicarbonate, pH, and lactic acid measures. All of these measures can be directly affected by individual toxins such that abnormalities may not indicate cardiovascular dysfunction in the poisoned patient. Therefore, all of these measures should be taken in aggregate and in consideration of the underlying toxic etiology.

In contrast to many victims of cardiac arrest for whom the event is relatively sudden, the poisoned patient has often had a protracted course of poor cellular oxygen delivery, either as a result of reduced respiratory effort or lung injury leading to impaired gas exchange, cardiovascular toxicity causing progressive prolonged hypoperfusion, alteration in hemoglobin-carrying capacity and oxyhemoglobin dissociation, poisoning of oxidative phosphorylation, or a combination of these. In the case of hypoxic cardiac arrest resulting from an isolated respiratory depressant agent, no ongoing toxic effect would be expected, and postarrest management would mirror that of patients whose arrest was nontoxic in etiology. However, in patients suffering cardiovascular toxicity, ongoing impairment of normal physiologic function will continue to complicate the postarrest course. As a result, patients are at very high risk of suffering ongoing perfusion deficits, brain and other organ injury, and subsequent cardiac arrest despite aggressive management.

Hemodynamic management following cardiac arrest from any cause involves first ensuring adequate volume resuscitation. Poisoned patients are frequently relatively volume depleted because of vomiting, insensible losses, and prolonged periods of unresponsiveness with diminished intake. Therefore, initial resuscitation with 1-2 L of isotonic solution, either normal saline or lactated Ringer's, is reasonable. Further volume resuscitation will vary among patients using end points such as measured urine output of at least 0.5 cc/kg/h, bedside echocardiographic evaluation of venous return, or central venous pressure, if available, of 8-12 mmHg. Patients with underlying heart disease or who are suffering inotropic

cardiac toxicity should be monitored closely for development of pulmonary edema.

Vasopressors

Following correction of hypovolemia and venous return, ongoing hypotension or hypoperfusion requires management with vasopressors and/or inotropes. Choice of vasoactive agents is frequently debated; however the data do not support superiority of any specific drug [27]. The choice of vasopressor typically reflects the primary presumed cause of hypoperfusion. Epinephrine may be chosen in a case of primarily cardiogenic shock or norepinephrine in a patient with combined cardiogenic and vasoplegic hypoperfusion. On the other hand, in patients with vasodilatory shock and significant tachycardia secondary to alpha-adrenergic blockade, phenylephrine may be preferred given its pure alpha-agonist effects without associated exacerbation of tachycardia. Norepinephrine, epinephrine, and, less frequently, phenylephrine may be employed individually or in combination depending upon the clinical scenario and pathophysiology of shock for each patient. More important than the specific agent chosen is attentive titration of the agent and response to such physiologic cues of peripheral perfusion as capillary refill and urine output as well as data indicating cardiac output and systemic vascular resistance when available. Bedside echocardiography may be useful in gauging cardiac contractile response to inotropic agents. An inotrope such as dobutamine may be employed as an adjunctive agent in the treatment of cardiogenic shock [28]. Finally, dopamine is associated with a greater incidence of arrhythmias in hypotensive patients [27]. Dopamine is also not an ideal agent in a poisoned patient population. As a mixed-acting sympathomimetic, vasoconstrictive activity is dependent upon indirect alpha-adrenergic effects at lower doses. While not specifically proven, toxicity from a reuptake inhibitor, such as a tricyclic antidepressant, could theoretically limit indirect vasopressor effect. As a result, likely because of dopamine's vasodilatory effect on splanchnic vascular beds, we have observed its use to be associated with exaggeration of

hypotension that improves with discontinuation. A distinction between patients suffering toxicity and other postarrest populations is the doses of vasoactive agents that may be required to achieve a desired effect. In many cases, vasoactive agents are being used to competitively displace a toxicant or overcome downstream inhibition of a desired metabolic pathway's effect. For this reason, vasopressors are best rapidly titrated to effect with continuous evaluation of markers of perfusion. This may require administration of doses not typically used in alternative diagnoses such as septic or nontoxic cardiogenic shock [29].

Poison-Based Interventions

Additional interventions that may be considered for the treatment of cardiovascular toxicity including glucagon, calcium salts, hyperinsulinemia-euglycemia (HIE), intravenous fat emulsion (IFE) or intralipid therapy, methylene blue, and specific antidotes will be discussed in the corresponding chapters. The potential benefits of these therapies in the treatment of a variety of cardiotoxic agents in addition to and, in some cases, in lieu of traditional vasopressor therapy has been debated [29, 30]. Unfortunately, the incidence and variable nature of severe toxicity leading to cardiovascular collapse and cardiac arrest render the disease process and therapeutic interventions difficult to study in a prospective, randomized way in human patients. Evidence for these interventions, therefore, is limited to animal models, case reports, and observational series. Review of these publications does not yield strong evidence to support any one treatment strategy in favor of another [31]. Nevertheless, given the refractory nature of severe toxicity, it is likely that patients suffering cardiac arrest will receive several or all of these therapies in addition to titrated vasopressor support in an effort to maximize all potential beneficial effects until toxicity has resolved. Potential complications of these measures must be anticipated and ameliorated.

Hyperinsulinemia-Euglycemia

High-dose insulin therapy has shown promising results in animal studies and human observational reports of beta-blocker and calcium channel blocker toxicity [30, 32]. Typical high-dose insulin dosing calls for initial bolus dosing of 0.5–1 U/kg followed by 1 U/kg/h infusion that can be rapidly increased, based upon clinical response, to doses of 10 U/kg/h or higher [30]. Administration of these doses of insulin carries the risk of clinically significant hypoglycemia and hypokalemia [31]. In the case of calcium channel blocker poisoning, hypoglycemia is rarely reported. But, blood glucose should be monitored frequently, especially at the outset of therapy in order to identify and treat hypoglycemia. Not only is early hypoglycemia a risk, patients on high-dose insulin would be expected to have residual hypoglycemic effects following resolution of acute toxicity. Once hyperinsulinemia therapy has been discontinued, frequent blood sugar monitoring should continue for at least 24 h [30]. In patients with acute kidney injury and impaired renal clearance of insulin, hypoglycemic effects may be even more protracted. In the postarrest population, periods of hypoglycemia have been associated with worsened neurologic outcomes further emphasizing the importance of vigilant glycemic monitoring with an ideal goal glucose range of 140–180 mg/dL [33].

Potassium supplementation is required for patients receiving high-dose insulin therapy. Significant hypokalemia, though primarily due to intracellular sequestration rather than decreased total body potassium load, can contribute to cardiac conduction abnormalities and lower the threshold for ventricular dysrhythmias. Another potential complication of high-dose insulin therapy is hypervolemia. The recommended dosing of insulin may result in the administration of hundreds of units of insulin per hour to a patient. Typically, insulin is mixed in crystalloid solution at a 1 unit/mL concentration. This can lead to the necessary infusion of multiple liters of fluid each day with the associated risks of pulmonary and peripheral edema in patients with impaired cardiac function [34]. Sequelae of volume overload

including prolonged ventilator dependence can complicate the ICU course and recovery following high-dose insulin therapy. Higher concentrations, including 16 units/mL, have been found to be stable and may mitigate the risk of hypervolemia [35]. High-dose insulin therapy is discussed in greater detail in the chapter devoted to its use and in the chapters related to specific relevant agents.

Intravenous Lipid Emulsion

Intravenous lipid emulsion (ILE) therapy with isotonic 20% long chain fatty acid solution for the management of lipophilic cardiotoxin poisoning has become widespread with an increasing volume of case reports and animal studies. ILE was initially identified as a resuscitation method for local anesthetic systemic toxicity in animal studies in the late 1990s and in human case reports beginning in 2006 [36]. Since then, successful ILE resuscitation of patients intoxicated with a variety of lipophilic agents (including bupropion, tricyclic antidepressants, β -blockers, and calcium channel blockers) has been reported [37]. While there are a multitude of positive reports, there are no human randomized trials to offer firm evidence of benefit, and the anecdotal reports may result in a publication bias inflating the perceived efficacy of ILE. Dosing of ILE is typically 1.5 mL/kg bolus followed by 0.25–0.5 mL/kg infusion [38]. Lipid rescue therapy, as it is sometimes referred to, might have antidotal activity through several proposed mechanisms: (1) introduction of an intravascular fatty compartment to absorb lipophilic drugs, the so-called “lipid sink,” (2) contribution of free fatty acids as a myocardial energy source, and (3) increased myocardial calcium concentrations mediated by triglyceride effects on cardiac calcium channels [39]. Several adverse effects attributed to ILE therapy have also been reported that could interfere with resuscitative efforts and contribute to therapeutic complications. ILE administration has been associated with acute lung injury, pancreatitis, critical laboratory interference lasting for hours despite ultracentrifugation of samples, and thrombotic phenomenon such as extremity deep venous

thrombosis [40, 41]. Additionally, lipid therapy has been associated with clotted lipemic blood obstruction of circuits in both hemodialysis and ECMO rendering these interventions ineffective [42, 43]. Based upon available literature comprised primarily of animal studies and human case reports, pending further study, it is reasonable to consider ILE therapy for patients suffering severe cardiovascular toxicity from a lipophilic drug that is unresponsive to standard interventions [40]. At the same time, indiscriminate use is not advised given the potential complication of ongoing critical care and resuscitation. In vitro and animal model investigation of liposome-based targeted antidotal therapy is also ongoing and may represent a future clinical therapeutic option [44]. ILE is discussed in greater detail in the chapter devoted to its use and in the chapters related to specific relevant agents.

Extracorporeal Membrane Oxygenation

Cardiopulmonary bypass (CPB) and ECMO, also referred to as extracorporeal life support (ECLS), offer management options for patients with cardiopulmonary failure unresponsive to medical and antidotal therapy. Deployment of ECMO is rapid and portable at centers experienced in the use of this invasive procedure offering benefits compared to formal CPB. It can be initiated through peripheral vascular entry at the bedside in the intensive care unit but is time and resource intensive. ECMO should only be performed at experienced centers with necessary institutional support and ancillary services [45]. Venovenous ECMO (VV-ECMO) is available for the management of respiratory failure without impaired cardiac function as has been seen in the management of critically ill patients with influenza. Venoarterial ECMO (VA-ECMO) can be used to support arterial perfusion in patients with cardiac failure as a temporizing measure until the underlying pathology improves or a permanent treatment, such as a ventricular assist device implantation or transplant, is performed and is considered a “bridge to recovery” [46]. Following placement of large bore percutaneous venous and arterial catheters, venous blood is removed, pumped through a circuit allowing oxygenation,

removal of carbon dioxide, and instillation of medications before being returned to the arterial circulation. Catheters may be placed in the groin or neck vessels. As acute cardiac failure secondary to intoxication would be anticipated to be a transient phenomenon, VA-ECMO is a reasonable consideration [47]. A number of case reports and observational studies have indicated successful management of drug-induced cardiovascular failure despite typical critical care management and improved survival rates regardless of the causative agent [48].

One observational non-randomized series of 62 patients with drug-induced persistent cardiac arrest or severe shock despite standard critical care management were treated with conventional therapy in one center vs. conventional therapy plus ECLS in a second center. In the ECLS group, 12/14 (86%) survived while 23/48 (48%) of the patients who did not receive ECLS therapy survived. One third of the ECLS group had ischemic or hemorrhagic complications requiring urgent vascular surgical intervention [49].

While results such as these are encouraging and merit further evaluation and investigation of the use of VA-ECMO in the management of toxin-induced cardiovascular failure, optimism must be tempered by the limitations of the available evidence including sample sizes and variability of treatment prior to the initiation of VA-ECMO. Additionally, VA-ECMO is associated with significant adverse events including life-threatening hemorrhagic and thrombotic events, limb ischemia, differential hypoxia, and pulmonary hemorrhage [46, 48]. Nevertheless, for cases of refractory toxicity and cardiovascular collapse in which all other available therapies have been employed without success, VA-ECMO is an appropriate consideration despite the lack of definitive evidence and associated risk as there are few, if any, alternatives. The optimal timing of initiation of therapy is another as yet unanswered question. VA-ECMO and other therapies stand a greater chance of success if instituted earlier in the course of treatment; however, this increases the risk of selecting patients that may not have required such heroic therapy and exposing them to the significant associated risk without

proof of benefit. Use of VA-ECMO in the treatment of cardiovascular toxicity and shock that fails to respond to conventional therapy requires further analysis but is a reasonable, ethical, and cost-effective therapeutic option in patients with a realistic expectation of meaningful recovery [48, 50]. ECMO and CPB use in the poisoned patient is discussed in greater detail in the chapter devoted to its use and in the chapters related to specific relevant agents.

Hypothermia

Therapeutic hypothermia (TH) has emerged as a critical part of postarrest care and has been associated with a significant improvement in survival and neurologic outcomes following out of hospital cardiac arrest [51, 52]. No prospective or randomized study of therapeutic hypothermia has been performed in patients following toxin-induced arrest to produce specific data suggesting benefit or harm of TH in this population. But, based on the large body of literature supporting its use after resuscitation of cardiac arrest from all causes, strong consideration should be given to its use.

There is debate regarding the optimal temperature goal in postarrest care. Most published studies have evaluated TH with a temperature goal of 32–34 °C, but more recent studies have shown similar results with targeted temperature management (TTM) at 36 °C [1, 53–55]. More importantly, hyperthermia is definitively associated with worsened outcomes after cardiac arrest and should be prevented in all populations [56]. Temperature management should be considered in any patient who is not following commands or showing purposeful movements following resuscitation from cardiac arrest. Generally, the only absolute contraindication is a known do not resuscitate order; however, this may be debated in the poisoned patient, particularly when self-inflicted harm as a result of a depressive episode is suspected. While future studies will determine optimal temperature for subgroups, it is reasonable to target the temperature for either 32–34 °C or 36 °C in the postarrest patient.

Prior to induction of either TH or TTM, patients should be intubated, sedated if necessary, and have a core temperature monitor in place. Core temperature monitoring is accomplished with, in order of preference, endovascular, esophageal, bladder, or rectal thermometer placement [57]. Brain injury and cerebral edema, frequently identified on CT scan of the brain, are common and deadly complications of prolonged hypoxemia and cardiac arrest [58]. TH is the preferred treatment strategy in patients with demonstrated or increased risk of intracerebral hypertension, cerebral edema, and postarrest seizure activity as there is evidence of reduction of intracranial pressure and seizure risk [59–63]. Once the goal temperature has been chosen, cooling typically begins by rapidly infusing 20–30 ml/kg of isotonic crystalloid solution stored at 4 °C. Each liter of 4 °C solution infused over 15 min decreases the core temperature by 1 °C, comparable to intravascular cooling devices [63–65]. Patients with compromised cardiac function, renal failure, or signs of volume overload and pulmonary edema may not be able to tolerate the necessary rapid infusions of this volume of fluid. Additional methods of cooling include surface cooling and placement of intravascular cooling devices. Surface cooling is achieved with cooling blankets (ideally placed above and below the patient), cooling vests, and placement of ice packs in the neck, groin, and axillae. Surface cooling has been associated with temperature decreases of 0.5–1 °C/h and is similarly effective as intravascular cooling [66]. Importantly, survival did not differ between surface and intravascular cooling groups; the decision on method to achieve goal temperature should be determined by the treating clinician.

A critical component in achieving and maintaining temperature, regardless of the goal temperature, is prevention and treatment of shivering. A natural response to TH and TTM, even subclinical shivering can complicate appropriate maintenance of temperature [67]. The shivering threshold in healthy individuals is approximately 36.6 °C [68]. Thus, temperature management at either 33 °C or 36 °C will require suppression of shivering [1]. Prevention of shivering primarily involves sedation. A number of agents have been

used with varying effectiveness. For the most part, sedative agents that have classically been evaluated are appropriate for and often used in the poisoned patient, including propofol, benzodiazepines, and dexmedetomidine. However, fentanyl and meperidine can be used as adjuncts to prevent shivering [69]. Given the serotonergic properties of both meperidine and fentanyl, treating toxicologists may want to avoid these medications in patients with known or suspected ingestion of a serotonergic agent. The combination may result in exacerbation of toxicity including increased hyperreflexia and tremor, which would further complicate shivering [70, 71]. Nondepolarizing neuromuscular blockers may also be used in the treatment of uncontrolled muscle activity or shivering, particularly when blood pressure will not accommodate further sedation. However, electroencephalogram monitoring is necessary in paralyzed patients given the risks associated with unrecognized seizure activity or nonconvulsive status epilepticus [72, 73].

Seizures

Seizure activity is a well-recognized complication of anoxic brain injury. A number of anticonvulsants including valproic acid, phenytoin, phenobarbital, midazolam, and propofol have been evaluated for the treatment of status epilepticus without clear superiority of any particular agent [74, 75]. A number of cardiotoxic agents are also associated with CNS toxicity and seizures. It may be difficult to differentiate seizures caused by toxicity versus those caused by brain injury. In the poisoned patient, treatment of seizure activity with agents exhibiting GABA-A properties such as propofol, midazolam, and phenobarbital is likely most appropriate as valproic acid and phenytoin are typically not effective, and potentially deleterious, in the management of most toxicant-induced seizures [76]. Poisoning-related seizures are discussed in greater detail in ► Chap. 20, “Toxicant-Induced Seizures.”

Drug Metabolism During Induced Hypothermia

Another factor to consider when managing patients following return of spontaneous

circulation after toxin-induced cardiac arrest with TH and TTM is the potential metabolic effect on drug disposition. At temperatures below 36.5 °C, midazolam clearance via CYP3A4/5 begins to slow and continues to decrease at lower temperatures [77]. Similar results have been found for phenobarbital, phenytoin, vecuronium, propofol, fentanyl, and morphine [78]. Based on these findings, it is logical to infer that temperature reduction may not only slow the metabolism of various therapeutic drugs but may have a similar effect on the toxic agent. Depending upon perceived ongoing toxic effects, rapid elimination of the offending agent may offset the potential benefit of hypothermia for neurologic recovery. No data exist to guide the toxicologist in selection of patients appropriate for induced hypothermia despite the potential delay in resolution of drug toxicity. However, at the very least, hyperthermia should clearly be avoided as discussed in the previous section.

Other Considerations in Hypothermic Patients

Additional complications of TH include impairment of normal coagulation, increased risk of infection after 24 h of cooling, bradycardia, QT interval prolongation, diuresis, hypokalemia, hypomagnesemia, and hypophosphatemia [79]. Hyperglycemia as a result of insulin resistance is another recognized complication of TH, which could have implications in the use of high-dose insulin therapy [80]. With the exception of hypokalemia, the rates of adverse events do not differ between TH and TTM [1]. Hypothermia-induced changes in arterial blood gas reporting must also be recognized when interpreting results [81] Table 3.

Table 3 Recommended adjustments to interpretation of blood gas findings during temperature management

Blood gas value	For every degree below 37 °C
PaO ₂	Subtract 5 mmHg
PaCO ₂	Subtract 2 mmHg
pH	Add 0.012 units

Rewarming

After the desired period of temperature management has been completed, slow and gradual rewarming should occur at a rate of 0.2–0.25 °C [82]. More rapid rewarming can result in nullification of the benefits of temperature management as well as adverse outcomes such as cerebral edema, seizures, hypoglycemia, and hyperkalemia [83]. As the patient is rewarmed, TH-induced changes can resolve very quickly necessitating frequent clinical evaluation and close laboratory monitoring of electrolytes and glucose.

Therapeutic Hypothermia in the Poisoned Patient

While TH has not been specifically prospectively evaluated in victims of toxicant-induced cardiac arrest, the demonstrated benefits observed in patients suffering cardiac arrest from any cause provide reasonable evidence to extrapolate results to the poisoned population. Postarrest physiology and associated neurologic injury are most likely applicable to patients regardless of the primary etiology of arrest. Several key distinctions must be considered in the toxic arrest patient. For instance, the inciting cause of toxicant-induced cardiac arrest has exerted its effect for a period of time prior to arrest and will continue to do so after the arrest. Typically, there is no definitive way to hasten the resolution of toxicity from agents not amenable to hemodialysis or other enhanced removal methods. Therefore, the benefits of TH in postarrest care should be weighed against the ongoing need to manage toxicity. In particular, it is unclear if induction of TH delays clearance of the offending agent to an extent that overall cardiovascular toxicity is prolonged. If so, the potential risk of TH may outweigh the clearly demonstrated benefits in nontoxic patients. In the case of CNS depressant toxicity, delayed resolution of toxic effects may prolong time on the ventilator but otherwise would be unlikely to significantly worsen overall outcome. In this case, TH following cardiac arrest is likely advisable. Patients suffering direct cardiovascular toxicity may benefit from TTM rather than TH as hypothermia may contribute to prolonged toxicity and

ischemic injury. In the end, decisions will need to be made by individual providers based on the specific illness of each patient as there is no universally applicable evidence to support TH after toxin-induced arrest. Regardless of temperature management strategy chosen, fever should be avoided.

Neuroprognostication

Predicting neurological outcome in the postarrest patient involves incorporation of data from a variety of different sources, including physical examination, somatosensory-evoked potentials, electroencephalography, and neuroimaging. Computed tomography of the brain should be performed on comatose postarrest patients. Intracranial hemorrhage complicates up to 7% of cases and cerebral edema is a grim prognostic indicator [58]. Electroencephalogram (EEG) monitoring of postarrest patients is also recommended. Nonconvulsive status epilepticus is a common finding on continuous EEG and is associated with poor survival and neurologic outcomes [73, 84]. Despite available adjunctive tests, early prognostication at 72 h remains difficult and likely insufficient to make a final determination of perceived outcome potentials [85]. Withdrawal of care based upon perceived neurologic injury and prognosis has been identified as the leading cause of hospital death in patients suffering out of hospital cardiac arrest [85].

The lack of reliable evidence to support early neuroprognostication would suggest that family discussions regarding final treatment decisions are done with the understanding that prediction of outcome is difficult and should be delayed, though optimal timing has yet to be elucidated. In the poisoned patient, this is particularly true as the potential presence of CNS depressant medications can further confound the issue. In addition to serial neurologic examinations, analysis of the presence of sedating agents in serum may be of use in determining the ongoing exogenous sedative effect [86]. In an effort to provide a more reliable neurologic examination in the comatose postarrest patient, reversal agents such as

naloxone and/or flumazenil may be considered. However, their potential utility as a diagnostic aid may be outweighed by the risk of inducing physiologically significant withdrawal symptoms including tachycardia, hypertension, seizures, and vomiting. Moreover, reversal of these agents may have a negative effect on neurologic recovery as studies have shown neuroprotective benefits of opioids and benzodiazepines [87, 88]. Prognosis of neurologic recovery should be delayed in the postarrest patient and include ongoing communication with the patient's family prior to making a final determination of viability or futility. In the toxicant-induced patient population, favorable neurologic outcomes have been observed despite typically poor early predictors [5]. This topic is discussed in greater detail in ► **Chap. 13, "Poisoning Fatalities."**

Clinical care of the seriously poisoned patient is usually multidisciplinary, commonly involving various medical specialists, including emergency physicians, anesthesiologists, intensivists, and toxicologists. The role of a psychiatrist is sometimes overlooked, especially in texts that focus on the ABCs (airway, breathing, circulation) of toxicologic management. Reviews of the topic often make little or no mention of the psychiatric management of these patients [1]. Yet patients who deliberately overdose have a high prevalence of suicidal ideation and pre-existing psychiatric disorders that may impact medical management [2], and it is also common for patients admitted to intensive care units (ICUs) to develop a psychiatric disturbance (e.g., delirium) during their admission, regardless of their premorbid psychiatric state [3]. Delirium is now being recognized as a condition to be prevented when possible and managed aggressively to minimize short- and long-term sequelae; therefore, psychobehavioral expertise is becoming vital in the critical care setting. Furthermore, drug misadventures in patients with addictive disorders comprise a growing percentage of acutely poisoned patients. Many toxicology patients have intentionally exposed themselves to their poisons, and a portion of those carry an elevated risk of subsequent suicide with a rate of 1.6% (CI 1.2–2.4) after 12 months and 3.9% (CI 3.2–4.8) after 5 years; and repetition of nonfatal self-harm or self-poisoning of 16.3% (CI 15.1–17.7) after 12 months [4], so attention to the psychosocial determinants of self-poisoning

and to underlying mental health needs is essential. This chapter outlines the psychiatric aspects of critical care toxicology and describes the potentially useful role of a psychiatric service in the multidisciplinary management of seriously poisoned patients. It is organized to mirror the temporal course of patient care and mental health issues that arise, from the precipitants of toxicologic exposure through the course of critical illness to post-recovery intervention.

Epidemiology

Serious poisoning has a spectrum of etiologies and manifestations. Various informal classifications exist (Table 1). Despite a lack of consensus in classification, it is well recognized that deliberate self-poisoning (DSP), recreational drug use, chronic substance misuse, iatrogenic poisoning, and accidental poisoning in children account for most cases requiring hospitalization and treatment.

One of the most widely accepted definitions of DSP is as follows:

The deliberate ingestion of more than the prescribed amount of medicinal substances, or ingestion of substances never intended for human consumption, irrespective of whether harm was intended. This definition takes an epidemiological stance, defining attempted suicide on the basis of behavior alone, rather than by an inference about intent [5].

There is still incomplete agreement, however, concerning the definitions used. Some large-scale

studies have preferred the term *parasuicide* [6, 7]. Attempts have been made to operationalize the definitions for all types of self-harming behavior [8] and for suicide [9]. Personal motivations in DSP are difficult to classify for many patients. Intensity of suicidal ideation can both surge and abate quickly over short periods of time, often substantially reduced by the time a patient reaches hospital. This observation may reflect ambivalence – the simultaneous experience of intense but opposing feelings – that has patients both wishing for death in the face of overwhelming upset and wishing for relief and care that would obviate the perceived need to be dead. Studies of personal motivation tend to suggest that communicating distress, expressing hostility, influencing others, relieving an unpleasant state of mind, and frank suicidality are all common. Patients with significant suicidal intent often disclose this early in assessment interviews [10].

In the United States, the National Co-morbidity Study reported a lifetime suicide attempt rate of 4.6% [11], and a Canadian study of school-age adolescents reported an attempt rate of 3.5% [12]. It is unknown what proportion of these attempts result in a presentation to hospital, but most hospital-treated events are due to DSP. Although institutional data is generally considered to be an underestimate of the true picture, a summary of the number of presentations and population-based rates of nonfatal hospital-treated DSP in the United States in 2013 is presented in Fig. 1. A study conducted in the mid-1980s reported that 5% of all ICU admissions in a US center resulted from a drug overdose [13], but this is likely to vary as a consequence of service mix and admission practices.

Deliberate self-harm (DSH) is a common reason for presentation to acute care, and DSP or overdose is overwhelmingly the most common form of DSH requiring general hospital admission and treatment [14]. In a year-long survey of 15 - European centers of all adult hospital-treated parasuicides, mean admission rates of 167/100,000/year for men and 222/100,000/year for women were reported, although there was wide variation among centers [15]. An epidemiologic center in Oxford, United Kingdom,

Table 1 Classification of poisoning types

Classification of overdose ^a	Classification of poisonings and envenomations ^b
Accidental	Deliberate self-harm
Suicidal behavior	Recreational
Recreational/experimentation	Accidental
Compulsive	Iatrogenic
Indeterminate	Envenomations
	Other

^aFrom Reilly et al. [305]

^bFrom Whyte et al. [26]

Fig. 1 Nonfatal deliberate self-poisoning in the United States, 2013

estimated the national DSH admission rate at approximately 400/100,000/year [16, 17]. Deliberate self-harm is one of the five leading causes of hospital admission for men and women in the United Kingdom, with DSP resulting in 150,000 hospital referrals a year [16, 18]. In the United States, DSP has been reported to account for 1% of all emergency department (ED) presentations, with a subsequent admission rate twice that for all other ED patients [19]. In Australia, one regional catchment center estimated a rate of approximately 200/100,000/year for hospital-treated DSP [20]. DSP may account for more than 5% of Australian general hospital admissions and almost 20% of all ICU admissions [21], although more recent changes in psychotropic prescribing, DSP trends, and acute hospital care routines are likely decreasing admission rates there and in other countries [22–24].

Not all cases of poisoning result in serious toxicity. Some units admit all presentations of DSP as a matter of policy, but this is by no means universal, particularly in the United States. In a New Zealand survey, 69% of all patients presenting with DSP were admitted to hospital,

with 10% admitted to the ICU [25]. There may be threefold to fourfold differences in the rate of direct discharge (nonadmission) from EDs in different settings, with 50% of patients with such presentations not admitted in the United Kingdom [16]. Emergency department staff are more likely to discharge patients without admission or psychiatric assessment when the presentation occurs before or after daytime business hours or on weekends [14], and more than 50% of all cases may present during these times [14, 26]. Definitions of toxicologically or medically serious cases also vary, although there is, at best, only a modest association between toxicologic severity and suicidal intent [27]. In New Zealand, a study of adolescents and young adults defined a “medically serious attempt” (at suicide) as one requiring hospitalization for at least 24 h and at least one of the following: treatment in an ICU, hyperbaric unit, or burns unit; surgery under general anesthetic; or medical treatment beyond gastric lavage, activated charcoal, or routine neurologic observation [28]. Older studies defined *medically serious* differently, reflecting the poisonings common at the time and a simpler approach to

classification (e.g., a coma level of particular severity, serum salicylate >50 mg/dL (360 μ mol/L), or carboxyhemoglobin $>30\%$) [27], or simply considered admission to the ICU or critical care unit (CCU) as appropriate to define a *serious poisoning* [29].

Poisonings from misuse of medications and addictive substances in adults are second in frequency to DSP, with alcohol and opioids being the most common agents used. Benzodiazepines, anticholinergics, cocaine, amphetamines, phencyclidine, and hallucinogens also are used recreationally and may cause serious toxicity. Psychotropics available over-the-counter like dextromethorphan are popular with adolescents, and a number of synthetic compounds that function as cannabinoids, serotonergics, and psychostimulants have taken hold in the toxicologic landscape via Internet commerce [30]. Other therapeutic compounds such as neuroleptics, antidepressants, and dopamine agonists also are used, albeit less frequently, as drugs of abuse and occasionally may produce toxicity. Even after patients survive acute poisoning, persistent psychosis caused by addictive substances like methamphetamine is a recognized phenomenon [31, 32]. Novel synthetic cannabinoids and phenethylamines may also carry risk for symptoms that require ongoing psychiatric treatment once acute intoxication has abated [33, 34], not unlike persisting perception disorders from lysergic acid diethylamide, psilocybin, or 3,4-methylenedioxymethamphetamine (MDMA) [35, 36]. In some instances, there may be serious long-term neuropsychiatric effects from drugs used recreationally (e.g., former users of MDMA may have memory impairment, which is related to the degree of exposure [37]), although these cases rarely require acute toxicologic intervention.

Iatrogenic poisonings may be a less frequent occurrence, but their potential seriousness should not be underestimated. Psychopharmacologic agents are frequently implicated in iatrogenic poisoning and may give rise to potentially fatal toxidromes, such as lithium toxicity [38], neuroleptic malignant syndrome (NMS) [39], serotonin syndrome [40, 41], and anticholinergic toxicity [42], and other serious systemic effects (e.g.,

cardiac arrhythmias, seizures, catatonia, pseudotumor cerebri, ataxia, nephrotic syndrome, priapism, or agranulocytosis) [43]. These complications occur more frequently in patients with a psychiatric history, even though the poisoning event is not driven by suicidal urges, addiction, or chronic misuse. Psychopharmacologic drugs of almost any class can produce serious toxicity in therapeutic use [44] and occasionally may give rise to a serious withdrawal syndrome [45], which may further complicate an admission for self-poisoning.

There is a degree of interplay between psychiatric illness and toxicity. Obviously, mental health difficulty is associated with DSP, with affective illnesses (major depressive disorder and bipolar disorder) and Cluster B personality disorders (borderline, narcissistic, histrionic, and antisocial) conferring the greatest risk [46, 47]. Borderline personality disorder (BPD) patients not only have the highest rates of repeat DSP and a 10% lifetime suicide rate [48], but their intensely shifting affects and behavior patterns along with high rates of polypharmacy and comorbid substance use can make critical toxicologic care even more challenging.

In any psychiatric patient, a new drug or increased dose of an existing drug can create a mixture of psychiatric symptoms and toxic effects that adds a layer of complexity to diagnosis and management. One example would be the case of a depressed patient whose therapy is changed from a tricyclic antidepressant to a selective serotonin reuptake inhibitor with an inadequate washout period, leading to a mixed affective state with features of both depression and mania that may evolve to frank serotonin syndrome with delirium [49]. Another example is a schizophrenic patient treated with antipsychotic medication who develops NMS and presents with symptoms of parkinsonism, rigidity, evolving malignant catatonia, and psychosis [50]; bromocriptine could alleviate NMS but worsen the psychosis. Still another issue is the role of addiction. Patients who misuse substances have high rates of mood disorders, anxiety, and behavior problems that can complicate assessment and management of toxicities and withdrawals. In cases of critical toxicologic

illness, standard protocols for management of agitation and use of sedatives to maintain mechanical ventilation may fail due to high levels of cross-tolerance and the emergence of withdrawal during the course of ICU care. A history of witnessing and experiencing trauma, which is common in patients with addictions and suicidal actions, also increases the likelihood of behavior disturbance in the clinical setting [51].

The elderly represent a demographic for whom there are unique psychiatric issues in critical care toxicology, as well. Although more DSP attempts are made by young people, death by suicide is more common with increasing age in certain segments of the population in the United States and some other industrialized countries [52]. Suicide rates in elderly white males are particularly high and have also spiked recently in those of late middle age who have occupational problems. One reason is the greater burden of medical illness that comes with age (especially chronic pain and cancer) and corresponding increased vulnerability to the impact of toxins. Additionally, older people have prescription medications available to them to manage those underlying conditions, medications which have narrow safety margins in overdose (e.g., antihypertensives, antiarrhythmics, heart failure agents, insulin, oral hypoglycemics, and anticoagulants). A baseline level of cognitive impairment is also more common with age, so older patients are more likely to experience delirium and more complicated hospital stays than younger adults when they suffer from acute toxicity [53]. Regardless of whether the cause is DSP, accidental poisoning, or iatrogenesis, the elderly are more vulnerable to protracted recovery and failure to return to a previous level of neuropsychiatric functioning [54, 55].

Childhood poisoning is usually accidental and tends to be associated with less morbidity and mortality than poisoning in adults, which is usually deliberate (suicide attempt or parasuicide) [56]. Nevertheless, a study of child psychiatric patients (<13 years old) found a substantial rate of self-reported suicide attempts [57], so an appropriate level of clinical suspicion is warranted. In addition, a larger proportion of young people with mental illness are being treated pharmacologically

for their conditions and gaining exposure to a wider variety of potentially toxic and sometimes addictive agents. Thus the use of prescription drugs in overdose by children appears to be increasing and the gender gap closing, with more boys taking purposeful ingestions in recent years [58]. More ingestions and other attempts with greater lethal potential are occurring in preadolescents as well [59]. Increasing rates of substance use problems in young people involving a variety of more acutely toxic agents also has led to more pediatric critical illness. Very young children and toddlers only rarely require admission to an ICU as a result of toxicity, and common household products are typically involved [60]. However, more prescription medications are now found in the environments where children live and play, and the ingestion of drugs such as clonidine, methadone, and buprenorphine does increase the likelihood of ICU treatment [61–64].

Although childhood poisoning is usually accidental, it remains a public health issue with psychiatric implications. Concern is growing for the toxic misuse of medicines by parents to address unwanted behavior in children. The administration of over-the-counter products for this purpose is not uncommon and results in a significant number of cases of morbidity and mortality in the United States each year [65]. Rarer types of poisoning include poisoning driven by factitious disorders like Munchausen syndrome or Munchausen syndrome by proxy. Although uncommon phenomena, these disorders can lead to serious toxicity, especially if the agents used are insulin [66], anticonvulsants, opiates [67], or laxatives [68]. The epidemiology of these conditions is hard to establish. A 2-year prospective study in the United Kingdom and Ireland reported 128 cases of Munchausen syndrome by proxy, nonaccidental poisoning, and nonaccidental suffocation in children younger than 16 years old, with an estimated rate of 0.5/100,000/year and a rate greater than 2.8/100,000/year in children younger than 12 months old [67]. Even the clinical classification of “accidental” childhood poisoning needs to be approached with some caution. A study of 50 childhood poisonings from a US poison control center documented recording of

“accidental” cases as “suicidal,” “intoxication,” and one attempted homicide with only a few remaining as “accidental” [69]. Whether or not a case clearly involves psychopathology in a child or unhealthy parent–child relationships, the majority of critical poisonings in this age group represent an opportunity to screen for psychosocial issues underlying the event, so the threshold for mental health consultation should be low (Level II-3 recommendation).

Roles for Consultation-Liaison Psychiatry

Psychiatry offers expertise in the interplay of central nervous system (CNS) function and behavior. Since the brain is the organ most commonly affected by acute poisoning [70], and patients with mental illness are overrepresented in critical care toxicology, there is clinical logic to support having a psychiatrist involved in the multidisciplinary endeavor of care. Consultation-Liaison (C-L) psychiatry is the subspecialty that manages the psychiatric needs of patients in the general hospital setting [71, 72]. This discipline, with formal training under the title of psychosomatic medicine, aims to maintain bridges between psychiatry and other specialties to provide biopsychosocial care to patients in nonpsychiatric settings [71]. *Consultation* generally refers to direct assessment and clinical management of individual patients, and *liaison* denotes coordination between and among treatment teams, families, and service organizations, sometimes without direct clinical contact with the patient [73–75]. In most clinical situations, a blend of these two modes is employed, with the latter time-consuming process often providing invaluable aid in supporting caregivers to help patients with complex patterns of illness. Toxicologists and other clinicians managing poisoned patients may choose to involve available C-L psychiatry services in patient care, or they may manage these patients entirely without psychiatric input (particularly in hospitals where consultation cannot be rapidly obtained). In the past, utility of psychiatric assessment has been questioned largely because

there had been no demonstrated effect on subsequent suicide deaths or repetition of DSP/DSH [76, 77]. Furthermore, acute and chronic problems related to addiction are frequently given differential (i.e., comparatively decreased) attention and resources in hospitals compared to those arising from DSP. As a result, practices vary widely across different countries and within different systems of care, from emergency departments to general medical floors and ICUs, regarding the involvement of mental health professionals of various kinds [26, 78–82]. But before the question arises of “what to do now that this toxic episode is resolved,” a host of issues surrounds the care of critically poisoned patients with which a C-L psychiatrist may be helpful.

From the very start of an episode of care in acute toxicologic practice, unique circumstances threaten to complicate the process. Stigma against mental health patients, pervasive in most societies and harbored by healthcare professionals at all levels, conspires against optimal treatment. Although not directly articulated, most caregivers have expectations for how patients should behave. Suicidal poisoned patients challenge expectations by participating directly in the cause of their own critical illness and sometimes obstruct workup and treatment by virtue of symptoms of mental illness that led to the toxic exposure. The ICU is a repository of finely honed lifesaving skills and high-technological equipment; yet these often limited resources are expended at times, in apparent paradox, in the care of patients who have expressed a wish to die. There may be a tendency for staff to consider aggressive lifesaving treatment in these patients as antithetical to the purpose of an ICU [83]. This attitudinal set represents not only a lack of compassion but also a failure to understand patients’ illnesses and motives. Even repeat attempters are not necessarily intent on ending their lives. Rather, they may be seeking relief or escape from intolerable feelings of hopelessness and despair, often complicated by problems of (negative) cognitive distortion and impaired problem-solving abilities [84], which may have their origins in childhood neglect [85], physical or sexual abuse [86–88], parental loss [89], family violence [89], or family histories of

depression, substance abuse, and parent–child discord [90] – all recognized risk factors for suicidal behavior in later life. Psychotropic medications are frequently prescribed to control symptoms in these troubled patients, and the very same medications are becoming more common in overdose attempts [24]. Many patients who ingest psychiatric medications may not be seeking death *per se*, but rather an obliteration of consciousness that has been fraught with overwhelming negative thoughts and emotions [24]. Patients who achieve relief in this manner and survive by virtue of advanced critical care may produce negative feelings in those caregivers who see them awaken from coma looking “fine” and “not suicidal.”

Although health care professionals may be less likely than laypersons to be judgmental in their attitudes toward attempted suicide, it also has been reported that medical staff may view attempted suicide merely as attention-seeking behavior [91]. In a study of almost 300 critical care nurses and more than 80 physicians working in Australian EDs and ICUs, it was found that both groups were frequently negative in their attitudes toward patients who had attempted suicide, with more than half considering parasuicide patients as manipulative [83]. Almost two thirds indicated that they did not enjoy caring for these patients. The results seemed to be independent of the gender or professional status of the respondent and of the number of years of experience in the critical care environment. A sense of frustration was a theme frequently conveyed through individual comments. This study suggested that it is common for physicians and nurses to have attitudes that would work against the establishment of sound therapeutic relationships with these patients. Similar negative attitudes toward DSP patients have been found in studies of junior physicians and nurses in the United Kingdom [92]. A Scandinavian study of 40 consecutive suicide attempters admitted to the ICU found that ICU personnel did not discern patients’ underlying feelings but responded to observable behavior, with reactions ranging from empathy to distancing and even to aggression [93]. Other factors that have been reported as contributing to negative

attitudes in ICU staff are perceptions of poor institutional support, a lack of positive reinforcement from the patients themselves, and inadequate educational preparation to provide optimal care for these patients [94], the lack of which conceivably could reinforce misconceptions and stereotypes that prevail in both professional and lay communities.

Appropriate nursing goals in the care of suicidal patients in CCUs have been identified and disseminated: developing an understanding of the patient’s response after a suicide attempt, accepting the patient in the unit, developing trust, conveying a sense of hope, providing psychosocial support, preparing the patient for discharge or transfer from the CCU, and managing problematic patient behavior [95]. Achieving these goals requires education, training, support, and reinforcement. Consultation-Liaison psychiatry staff, sometimes accompanied by nurse educators, may be invaluable in helping ICU staff to develop the skills necessary to meet these goals while adequately managing their own experience of the patients and the work. Teaching and modeling can help staff to understand how “manipulative” or “difficult” behavior may reflect patterns of human adaptation to trauma and stress that improve with attuned caregiving [96]. (Level I recommendation) Based on models developed at the Massachusetts General Hospital, a number of acute care practices have found value in having early intervention and routine guidance from C-L Psychiatry in the treatment of mental health patients who are critically ill, with special attention to the psychological impact of such cases on caregiver staff [97]. Knowledge of this type can foster the empathy necessary to manage mental illness comorbidity in DSP patients.

Additional skills and support can often be necessary to work with families of toxicology patients. DSP patients frequently experience relationship problems and psychosocial disadvantage [98, 99], so it is not merely the care of the critically poisoned individual that can be complicated by interpersonal unrest. For patients who have attempted suicide, relationships with family or significant others may be strained by events leading up to the suicide attempt and/or may be

chronically dysfunctional. Family or significant others may express ambivalence or hostility and aggression toward the patient and be unable or unwilling to provide even limited support [100] or direct these negative feelings toward staff, or the medical care process, itself. Family members may withdraw support from the patient or even file “do not resuscitate” orders – sometimes as a form of “passive euthanasia” [101]. This may reflect ambivalence in pre-existing relationships or the inability to deal with a deteriorating depression with suicidality that preceded the self-poisoning episode. Even when family and others intend to offer support, a patient who *perceives* his or her social or familial support as inadequate or falling short of what he or she needs may reject or frustrate further efforts of support. A patient acting on this perception then may engender feelings of rejection or indifference in others – family, friends, and caregivers alike – thus exacerbating the patient’s sense of isolation [102–104].

Psychobehavioral Problems

Seriously poisoned patients may exhibit a range of behavioral disturbances resulting from delirium, agitation, anxiety, suicidal ideation, relationship problems with staff or family, personality traits, persecutory delusions, hallucinatory phenomena, misunderstandings, pain, withdrawal, or a combination of these and other factors. For patient safety and comfort, treatment requirements, and staff safety, there may be occasions when it is necessary to reduce the degree of behavioral unrest. Toxicologic practice may largely focus on pharmacologic management strategies. Psychiatric perspectives can be helpful in this arena as well. But before simply intervening with sedatives, an understanding of the principles of “abnormal illness behavior” and “abnormal treatment behavior” may be useful in harnessing the power of interpersonal therapeutics [75, 102, 105, 106]. An important point to consider is that patients’ unrest usually involves some interactive influence of service providers; conflicts do not emerge from a psychosocial vacuum. This understanding may suggest strategies

for change within the treatment system and opportunities for direct, nonpharmacologic management of the patient.

Cognitive and behavioral interventions are common modes of effective nonpharmacologic intervention currently used. The more sophisticated forms of these psychological interventions are not generally applicable while the patient is in the ICU and are deployed more usefully during the recovery phase. (Level III recommendation) Nuanced understanding can enhance caregiver satisfaction and support empathy, but most useful interventions do not involve the patient’s direct participation in such insights. As has been noted for patients with the condition that produces the highest rates of repeat DSP episodes, BPD, “[i]n the medical setting, psychoanalytic interpretations of the unconscious are destined to fail; noninterpretive behavioral approaches are the ones that work” [103]. Practical, concrete interventions are usually of greater use during the period of treatment for severe toxicity.

Impact of the Hospital Environment

The nonmedical aspects of management of a self-poisoned patient in the intensive care setting – aspects of care that relate to the patient’s cognitive, emotional, behavioral, and psychological state, as opposed to the requirement to address ABCs of emergency management and detoxification – are important. Psychological disturbance associated with ICU admission is well described even in patients without prior psychiatric morbidity. Disorientation, restlessness, agitation, confusion, and frank delirium are seen frequently in ICU patients regardless of the reason for admission. Many aspects of the intensive care environment are in themselves sufficient to produce psychological disturbance. The ICU is an intrinsically frightening place – it is difficult to imagine a more disturbing experience than the gradual or sudden regaining of consciousness coupled with the realization of the presence of an endotracheal tube and mechanical ventilation. ICUs often do not respect the distinction between day and night; they may be uncomfortable, confusing, and

disorienting places, which can contribute easily to a patient's sense of depersonalization.

Despite these challenging experiences that frequently contribute to behavioral disturbances during an episode of critical care, it has been suggested that most patients have little or no memory of their stays in an ICU [3]. More recently, though, it has been recognized that medical trauma including the influence of an intensive care unit admission and memories of it can play a major role in the development of mood and anxiety disorders. Post-traumatic stress related to intensive care can be particularly problematic. Rates of both of these classes of mental disorders range from 8% to over 50%, with the likelihood being greater for those with premorbid mental illness [107, 108]. Since the majority of toxicologic patients have one or more pre-existing psychiatric diagnoses that contributed to their need for such medical intervention (e.g., mood disorder driving suicidal behavior), they comprise a particularly vulnerable population with respect to trauma-based iatrogenic mental illness. Most patients who do develop symptoms from medical trauma will require long-term follow-up, as depressive symptoms often fail to remit until at least the second year after an ICU stay [108], and post-traumatic stress disorder (PTSD) symptoms tend to persist even longer [107].

Delirium has been recognized as an independent risk factor for development of psychiatric illness in the wake of medical trauma. In addition to delirium, amnesia for the early portion of hospitalization, lack of education and social support, trait anxiety, and female gender all make PTSD a more likely sequela [109]. Risk factors for depression are similar, with delirium being a major covariate, along with an independent, dose-dependent risk from exposure to benzodiazepines in the ICU [110, 111]. Some types of poisoning (e.g., organophosphate poisoning, lithium toxicity, anoxic injury from opioids) may lead to prolonged stays in the ICU and require a range of invasive procedures. This prolonged exposure to traumatic events and mind-altering medications may increase the risk of protracted delirium and corresponding long-term psychological sequelae.

Strategies designed to prevent and minimize the severity of delirium are therefore critical in the acute toxicology patient (see text written below – v.i. – Delirium). In considering the causes of psychological disturbance, the full panoply of organic comorbidities and the effects of their treatment must be considered in addition to the primary reason for admission. Recognition of and attendance to reversible causes of anxiety also should not be overlooked; alongside the pathophysiologic effects of poisoning, these patients equally can be in pain, experience cold, develop sepsis, have blocked catheters, suffer constipation, or be in alcohol or other drug withdrawal. With attunement to these issues, ICU staff may be able to manage some level of psychological disturbance without particular need for formal psychiatric input [104, 112].

Delirium

Delirium is common in ICU patients, especially for those with a period of mechanical ventilation; it is often undetected and is associated with a range of poor short-term outcomes. It is a syndromic condition associated with increased rates of morbidity and mortality, both from its serious underlying causes and from complications of its behavioral manifestations [113]. However, we know of no outcome studies specifically restricted to critical care toxicology patient populations and so must take some general guidance from the studies of all ICU patient populations, while studies of critically poisoned patients are awaited.

A recent systematic review of 42 studies (observational and clinical trials) reported delirium in 31.8% of critically ill patients. Patients with delirium had higher in-hospital mortality (RR 2.19, 94% CI 1.78–2.70); longer durations of mechanical ventilation (SMD 1.79 (95% CI 0.31–3.27); longer ICU lengths of stay (SMD 1.38, 95% CI 0.99–1.77); and longer hospital lengths of stay (SMD 0.97, 95% CI 0.61–1.33) [114]. It is important not to ignore these important outcome data, even though the majority of acute toxicology patients are both expected to

experience delirium by virtue of their intoxicants and expected to survive due to the particular characteristics of their critical illnesses. Optimal management of delirium depends upon the systematic detection thereof, along with a targeted approach to care that does not rely simply upon pharmacological interventions. Psychiatry identifies a state of delirium as being defined by the core features of disturbed attention and awareness along with impairment of least one other mental process referable to cerebrocortical function [115]. This fluctuating pathological state represents a relatively rapid change from baseline that cannot be better explained by a pre-existing condition but is driven by an underlying medical problem. Note that sensory disturbances and corresponding delusional misperceptions of reality can occur, but psychosis is not synonymous with delirium nor is it required for the diagnosis. This distinction is critical. If behavior disturbances in toxicology patients are too quickly attributed to underlying psychiatric problems or assumed to be “just part of the intoxication,” not only can other acute medical conditions go untreated, but the physical (e.g., restraints, catheters, respiratory tubes) and pharmacologic tools employed to control behavior can also, themselves, cause further harm.

Validated instruments for the detection of delirium in ICU populations are available if not consistently used and include: the Confusion Assessment Method (CAM), the Confusion Assessment Method for the Intensive Care Unit (CAM-ICU), the Intensive Care Delirium Screening Checklist (ICDSC), the Neelon and Champagne (NEECHAM) Confusion Scale, the Memorial Delirium Assessment Scale (MDAS), and the Delirium Rating Scale (DRS) [114]. An older systematic review of drug induced delirium (not restricted to critical care populations) recommended an integrated clinical approach: recognition, cessation or dose reduction of causative drug(s), reorientation strategies, and supportive medical care; with specific “antidotes” appropriate in some cases. Recommended pharmacological treatment aimed at sedation for specific indications, such as aggression, risk of harm to self or others, hallucinations, patient distress, and for compliance with procedures was limited

to some benzodiazepines (diazepam, lorazepam, midazolam) and/or haloperidol [116]. (Level II-2 recommendation) In the intervening years there has been the development of specific clinical implementation pathways using these general principles, although the content of specific programs can be quite different. The choice of possible medications to manage delirium and its associated behavioral manifestations has also expanded, although the evidence base for which drug (route of administration and dose) to choose, and for which clinical endpoint, remains lacking (v.i. Pharmacologic Management of Psychobehavioral Disturbance).

A recent systematic review of interventions (clinical implementation programs) to identify and treat ICU delirium identified 21 studies, 9 of which reported clinical outcomes. Meta-analyses showed reduced mortality and ICU length of stay for: implementation programs using six or more strategies; using an integrated framework of current evidence on pain, agitation, and delirium management (PAD) or using a strategy of early awakening, breathing, delirium screening, and early exercise (ABCDE bundle) [117]. (Level II-1 recommendation) A narrative review of ICU delirium expanded the management of delirium further to include the “triad” of pain, delirium, and agitation as being commonly linked; and thus indicating that sedative drugs should only be used when pain and delirium have first been addressed with the use of specific pharmacologic and nonpharmacologic strategies [118]. (Level III recommendation) Integrated clinical approaches or clinical guidelines to address these complex and interacting aspects have been developed and published in the public domain [119]; and although these approaches are not specific to toxicology populations, the use of a systematic approach within a given clinical unit has merit (Level III recommendation).

Nonpharmacologic Management of Psychobehavioral Disturbance

Guidelines for managing delirial signs without medications share common procedures. Many of

the principles for managing anxiety are similar to those for delirium [120], and recommendations for recognition, assessment, and treatment of anxiety in CCUs are also available [104]. There are a number of simple nonpharmacologic strategies advised for the critical care of all patients that can minimize psychosomatic stress to the acute toxicology patient. Fundamental to these environmental strategies are the goals of orientation and reassurance. (Level II-1 recommendation) Key supportive measures include minimizing noise and sleep disturbance, providing levels of stimulation matched to the time of day, arranging appropriate ambient lighting or proximity to natural light, and displaying personal objects and photographs of familiar faces. (Level II-2 recommendation) Minimizing sensory impairments (e.g., providing eyeglasses and hearing aides) is essential to the efficacy of some interventions. In addition, ensuring consistency of staff members; giving simple and repeated explanations; and facilitating communication with symbols, charts, writing boards, and pointing devices for intubated patients, all minimize medical trauma. (Level II-3 recommendation) One powerful evidence-based tool for preventing ICU trauma from leading to psychological sequelae is the use of medical diaries. (Level I recommendation) Helping patients to document and make sense of their ICU experiences reduces incident PTSD within the months following an episode of critical care by over 50% [121].

Flexible visitation schedules to facilitate family and social supports are also valuable in managing anxiety [104]. (Level II-3 recommendation) Where possible, relatives or significant others should be encouraged to participate in communication and reassurance. Their efforts can be vital in the coordinated treatment of a delirious patient, so caring for these caregivers is important. It is essential that ICUs have designated spaces for promoting effective communication with families – comfortable, nonthreatening places offering quiet and privacy, physically removed but not too distant from the unit. Attitudes of relatives are difficult to optimize in ICUs that lack appropriate places where relatives are able to speak with patients or staff. Relatives are frequently upset

and when upset are more likely to misinterpret communications with staff [93, 122]. They, too, experience medical trauma while enduring the critical illnesses of their loved ones. Symptoms of anxiety, depression, and PTSD are common and do not always abate even when patients have recovered and are ready for discharge [123], so psychiatric consultation to families of toxicology patients can be beneficial during the phase of ICU care and beyond (Level II-3 recommendation).

One aspect of critical care that can be particularly disturbing for patients' families is the appearance of a body invaded by tubes and wires and occasionally held down by restraints. Historically the use of physical restraint for management of behaviorally disturbed patients with delirium was more common than it is today [124]. Most mental health legislation and case law emphasize the principle of preference for the "least restrictive alternative" form of care. The American Psychiatric Association Task Force's report on seclusion and restraint has suggested possible indications for use, as follows: the prevention of imminent harm to self or others when other methods are ineffective; the prevention of substantial damage to the physical environment; the prevention of serious disruption to the treatment program; as a contingency in the treatment of dangerous behavior; to decrease stimulation; and at the patient's request [125]. Although these indications are not universally agreed upon and were outlined decades ago to apply in psychiatric treatment settings, they might be relevant to seriously poisoned patients now. (Level III recommendation) Restraints are not without their proponents and potential usefulness, although a balance between the benefits and risks in each case should be made in light of available evidence [126]. Perhaps the best indications for effectiveness are for the prevention of injury and reduction of agitation in inpatient psychiatric settings [126]. The usefulness of restraint for these purposes may not always translate to medical settings, and the indications may be less clear. Restraint may be deemed necessary when patients directly interfere with lifesaving treatments, but it is not without serious physical risk in itself. A

review of physical restraint in medical settings suggested there is a strong likelihood that deaths resulting from the practice are underreported, with severe injuries typically due to strangulation, circulatory compromise, or neuronal damage [127].

In addition to physical injuries, physical restraint has adverse psychological effects on patients [127] and staff [126]. Staff training in the prediction and prevention of violence may be valuable in reducing the rates of usage and resulting untoward effects of restraint [126, 128]. (Level II-3 recommendation) Physicians and patients in a psychiatric setting reportedly favored psychotropic medication over physical restraint [129]; it is our position that critical care toxicologists should agree with this perspective. There is a reported continuing decline in the use of physical restraint in CCUs in response to ethical and clinical concerns [124, 130], so unless the medical situation requires (e.g., a brain injured patient with dangerous behavior needs frequent neurologic reassessments), physicians with advanced expertise in pharmacology are encouraged to use the less traumatizing modality of medication for treating confusion and agitation (Level II-3 recommendation).

Pharmacologic Management of Psychobehavioral Disturbance

There is far from a consensus on the appropriate drug, dose, or route of administration to be used to address disturbed behavior, whether associated with delirium or other psychiatric condition. Few randomized controlled trials have been undertaken with clearly defined toxicology or DSP patient samples to guide choices, but there are reviews outlining medical and pharmacologic principles that should be followed [116, 120, 131]. The most important maxim is that medicine seeks the underlying causes of signs or symptoms and, when possible, treatments should be chosen that target etiologies. In some psychosomatic states, following this principle can be challenging, and since C-L psychiatry routinely contends with such complex cases, consultative input may help to choose management strategies and even assist

in the medical detective work involved in sorting out those multifactorial underlying causes of behavior disturbance [113]. There should be clearly defined indications for the use of medications in each case, because not all behaviorally disturbed patients may require them [116]. This point is critical, because choosing optimal pharmacologic interventions depends on the current state of neuropsychiatric functioning in addition to the attendant evolving toxicologic acuity and comorbid mental illness burden. (Level III recommendation) We therefore subdivide considerations for pharmacologic management into initial acute interventions for the new onset of agitation and subacute interventions for ongoing behavioral unrest.

Acute Treatment

A general algorithm for choosing medications for acute management of agitation is outlined in Fig. 2. Note that the first decision point involves determination of whether or not the observed psychobehavioral unrest is a reflection of delirium or the direct effects of an intoxicant. Assessment of the latter is addressed in other chapters of this text. Common tools available for identifying delirium (see text written above – *vide supra*. – Delirium) may take more time than is available in the care of an acutely poisoned patient and agitation may interfere with the process. A “micro-mental status examination” focused just on the individual’s orientation, attention, and short-term working memory may be better suited to the care of poisoned patients [132, 133] – with any gross deficit leading down the pathway that prioritizes delirium workup and management. (Level II-2 recommendation) Impairments in these basic cortical functions should never be ascribed merely to volition or mental illness with medications chosen to extinguish undesirable behavior.

Noting the short-term medical and long-term psychiatric dangers of delirium (v.s.), if direct treatment or a potentially beneficial antidote is available for a suspected cause, it should be administered. Examples include delivery of oxygen to a confused hypoxic patient and interventions to raise blood pressure in a patient with failing mental status from hypotension. Central

Fig. 2 Algorithm for pharmacologic management of acute agitation

nervous system antidotes also fall under this category. Naloxone is routinely employed to arouse patients from opioid-induced stupor. Flumazenil will reverse delirium from GABA-ergic toxins [134] and can be safely used in patients whose presentation is consistent with sedative toxicity (DSP or iatrogenic), even in the presence of comorbid neurologic and psychiatric illness, and in those who chronically take benzodiazepines [135]. (Level II-2 recommendation) Physostigmine is indicated to directly treat anticholinergic delirium and can be safely employed when cognitive impairment is suspected from a variety of compounds commonly involved in cases of DSP, including cyclic antidepressants [136]. (Level II-2 recommendation) Central nervous system antidotes help patients to assist in their own care and contribute vital information both about the causes of their distress and about other issues of medical and toxicologic import (e.g., sources of pain, focal dysfunction, toxic coingestion) (Level II-3 recommendation).

If such a specific intervention is not available and/or the underlying cause unclear after

assessment and use of antidotes, then one further question should be addressed. If the suspected differential diagnostic list of potential etiologies involves significant immediate risk of seizure or arrhythmia, then the initial medication choice for agitation should involve benzodiazepines; evidence supports their use alone or in combination with haloperidol [137]. (Level II-1 recommendation) If an adverse electrical event at the level of the heart or brain is not likely, then antipsychotic medication alone is safe and preferred to preserve cognition and avoid adverse effects of benzodiazepines [138–140]. (Level II-2 recommendation) The choice of a specific agent is complex and not clearly established in the literature, so local variation in practice is common. A consensus workgroup of emergency providers relying on meta-analytic review to outline best practices in evaluation and treatment of agitation (Project BETA) recommends atypical antipsychotics over butyrophenones [140] (Level II-3 recommendation), but it should be noted that the anticholinergic activity of certain agents (e.g., olanzapine, quetiapine) could worsen confusion in some

cases of toxic delirium. (Level III recommendation) Although there is concern about the potential for extrapyramidal reactions from haloperidol, the risk is vanishingly small in patients with delirium. Their cognitive impairments reflect functional CNS hypocholinergia (with impaired memory, attention, communication, and decision-making), so even robust dopamine blockade rarely causes imbalanced neurotransmission that results in movement side effects. Additionally, there is evidence for rapid cognitive improvement from intravenous haloperidol infusion through positive effects on hippocampal and frontal lobe function [141]. Such benefits support the recommended use of first generation antipsychotics (like haloperidol) for management of disinhibited agitation in alcohol intoxication [140], which can be exacerbated by GABA-ergic agents. (Level II-3 recommendation) Of course, all dopamine blockers must be avoided if antipsychotic medications are a suspected cause of a patient's delirium as a consequence of NMS.

Should delirium or severe intoxication not be present, medication choice largely turns on the presence or absence of psychosis. Psychobehavioral unrest driven by delusions and/or perceptual disturbances is best treated with antipsychotic medication. In this clinical scenario, Project BETA recommends the use of atypical agents that antagonize both dopamine and serotonin pathways based on data favoring better subjective patient experiences and milder side effect profiles [140]. Butyrophenones produce more dysphoria in nondelirious patients (Level II-3 recommendation), and the risk of extrapyramidal movement problems makes an oral offering of risperidone or olanzapine a more favorable option as well [140]. (Level II-2 recommendation) If delirium has just resolved or remains a significant risk, however, the antimuscarinic activity of olanzapine (or quetiapine) may be less desirable in the potentially complex pharmacologic situation of acute poisoning. Under such circumstances risperidone, ziprasidone, or a judicious dose of haloperidol may be best, avoiding cognitive impairment from anticholinergia. (Level III recommendation) If a patient is unwilling or unable to take medication in oral form, parenteral

options are available for ziprasidone, olanzapine, and aripiprazole – the latter is not recommended in the acutely poisoned patient due to a higher risk of akathisia (which may worsen agitation) and an array of effects on serotonin neurotransmission that can complicate toxicologic care [142] (Level II-3 recommendation).

In the agitated patient without delirium, psychosis, or intoxication, an effort should be made to engage in communication that will help to discern the underlying cause of distress so it may be addressed directly. (Level II-2 recommendation) If the subjective complaint is pain, analgesia may calm behavioral unrest. In patients with low distress tolerance who are hungry, thirsty, lonely, or overwhelmed, nonmedication solutions may be available. Some subjective upset can be calmed with medications – benzodiazepines are useful for anxiety or emotional anguish and atypical antipsychotics better address anger or fear [140]. (Level II-3 recommendation) If the patient cannot be engaged to discern a specific target for intervention and the physical threat from agitation is high, benzodiazepines and antipsychotics are the evidence-based options to ensure safety. Project BETA recommends oral offerings first, but parenteral delivery may be necessary. Clinical experience and some research suggest that when danger is very high and rapid tranquilization desirable, an injection of both haloperidol and lorazepam may be the best choice [137, 140]. (Level II-3 recommendation) (Note that most extrapyramidal reactions occur several hours after acute dopamine blockade, so despite being common in practice, the “prophylactic” use of parenteral anticholinergics along with haloperidol has little evidence and may impair cognition.) A randomized trial in potentially violent patients showed rapid efficacy with droperidol alone or in combination with midazolam, along with a superior physical side effect profile to midazolam alone [143]. (Level I recommendation) However, in some countries including the United States, this butyrophenone may be unavailable for use due to the impact of warnings, such as those from the Food and Drug Administration, about the potential for fatal arrhythmias. Such adverse events are rare, and a recent study demonstrated

minimal risk of repolarization anomalies with droperidol [144].

Very recently, intramuscular ketamine has been used for sedation of severely agitated patients as well. Caution should be exercised in the DSP population, however, as emergence reactions and persistent psychiatric symptoms related to the dissociative agent are more frequent in patients with mental illness and trauma histories – two common comorbidities in acute toxicology. (Level II-3 recommendation) Choosing high dose ketamine may also be complicated by the sympathomimesis and neuropathology of toxic states [145] along with pre-existing neurophysiologic vulnerabilities [146] for which benzodiazepines and dopamine blockers would be potentially safer.

Ongoing Treatment

Psychiatric consultants may not routinely be involved in the early course of behavioral management in toxicologic critical care when decisions about acute interventions are made. The principles outlined above are valuable throughout the course of treating DSP patients, even though some may appear to apply largely after the critical phase of toxicologic treatment has passed and mental health consultants are called to determine next steps in management and disposition. Even if C-L psychiatrists are involved earlier in the course, they may be less likely to contribute recommendations for maintenance of sedation and breakthrough agitation in the ICU, as such choices are viewed as the purview of critical care teams [147]. Noting the implications of delirium and complications from agitation, though, having a psychiatric perspective to augment a more comprehensive treatment plan may be worthwhile; practice guidelines are beginning to reflect this appreciation [148–150] (Level III recommendation).

Despite their utility and widespread use, benzodiazepines have long been a source of concern for psychiatric consultants who manage delirium in the acute care setting [120]. Continuous infusions of midazolam remain common practice with apparent benefits that fit with ICU nursing routines [151], even though interrupted regimens have been associated with decreased sedative

use, lower rates of delirium, fewer complications, and shorter lengths of stay; and thus appear in the most current practice guidelines for critical care [148]. When these agents must be employed, intermittent pro re nata dosing of a compound with reliable pharmacokinetics and without long-acting metabolites (e.g., lorazepam) can achieve desired results using less medication and shorter duration of treatment as demonstrated in the case of alcohol withdrawal [152]. (Level II-2 recommendation) Decreasing amount and duration of exposure to benzodiazepines is an important goal, since they yield an independent, dose-related risk of delirium [139]. Flumazenil can be used to reverse iatrogenic oversedation and delirium and support progress in recovery [135, 153]. (Level II-2 recommendation) Treatment of ICU patients with melatonin has been shown to help in maintaining circadian rhythms and promoting restful sleep with a concomitant decrease in sedative use [154] (Level I recommendation).

Even with these enhancements, escalating doses of sedative medications may still complicate the care of toxicology patients. The role of underlying substance use disorders is a fairly obvious but often neglected factor. Cross-tolerance between the agents chosen for sedation and drugs of abuse, including alcohol, may drive critical care teams to employ very large doses of benzodiazepines to control behavior – sometimes due to concern for emerging withdrawal in a ventilated patient. Although withdrawal can be problematic and severe, careful attention to neurologic examination and autonomic indices may help to identify when patients require withdrawal treatment and when patients' agitation can be safely managed with antipsychotic medications that circumvent cross-tolerance, minimize sedative use, and preserve cognition. (Level III recommendation) Nonaddictive agents like alpha-2 receptor agonists (e.g., clonidine, guanfacine, dexmedetomidine) may also be useful in toxicologic and withdrawal states to provide sympatholysis and calm without exacerbating delirium [155]. (Level II-1 recommendation) A number of studies suggest that managing withdrawal states and anxiety in addicted patients with medications like clonidine and

anticonvulsants (e.g., carbamazepine, valproic acid, gabapentin) that do not reinforce drug use correlates with much higher rates of pursuing sobriety after an acute episode of care [156]. (Level II-2 recommendation) Balancing good principles of toxicologic management with psychiatric guidance that helps to minimize cognitive dysfunction and negative impact on addictive diatheses is key to optimal management.

As an adjunct or alternative to benzodiazepines, opioids have gained wider use in ICU sedation regimens in recent years [148]. Noting that pain frequently accompanies critical illness states, the term “analgo-sedation” has been used to describe this practice. Since a large percentage of toxicology patients are not plagued with pain, however, the routine use of opioids for this subset of ICU patients comes into question, especially in light of the potential for adverse effects that can interfere with treatments (e.g., gastrointestinal slowing that complicates activated charcoal administration) and with patients’ cognition and behavior. Morphine may be particularly problematic due to the effects of delirigenic metabolites, especially in patients with renal impairment [148]. This added risk does not appear to be mediated by mu opioid activity, as naloxone is not a reliable antidote. Other opioids can be delirigenic, as well, with continuous infusions further increasing the likelihood of cognitive impairment [150]. (Level II-2 recommendation) Even though a dose relationship remains, the risk of delirium may be lower with fentanyl as compared to other opioids [148, 157, 158]. However, like the other phenylpiperidine opioid meperidine, fentanyl can contribute to serotonin toxicity and should be avoided in the ICU management of patients who may have been exposed to serotonergic agents [159]. (Level III recommendation) Noting the ubiquity of psychotropic drugs and abusable substances that enhance serotonin activity, the routine use of fentanyl for sedation in critical care toxicology cannot be recommended. Other opioids, including buprenorphine, may have a role if the issue of withdrawal from this class of agents is clearly complicating management [160] (Level II-3 recommendation).

In general, psychiatric perspectives on therapeutic sedation and management of delirium would likely advocate more frequent use of antipsychotic medication with corresponding decreases in the use of benzodiazepines and opioids. Cochrane reviews on pharmacologic interventions for delirium support this position [161, 162]. (Level II-2 recommendation) Data reviewed to guide care in the United Kingdom National Health Service are consistent as well [163]. (Level II-2 recommendation) Preservation of cognition in the face of acute, stressful illness is a central goal. While some critical care providers may believe it would be more desirable to sleep through the discomforts and confusion of critical illness, both short- and long-term measurable outcomes suggest otherwise [164, 165]. In addition, psychiatrists are attuned to the impact of reinforcing substances on health and behavior, so a C-L consultant will look to weigh risks against the benefits of using narcotic agents in the ICU – especially with patients who already struggle with addiction.

Psychiatry defines many of the ways in which toxicology patients differ from the average patient characteristics in ICU medicine. Although they tend to be younger and more physically resilient, toxicology patients have some unique issues and vulnerabilities to be considered in optimizing critical care. In addition to the pharmacologic concerns that accompany individuals with a predilection to self-exposure to toxins, underlying mental illness itself may impact responses to medications. Patients with obsessional personality traits and those who have experienced significant trauma more frequently react poorly to being maintained in states of partial awareness with sedative medications. Borderline personality disorder, a condition usually associated with trauma, carries a high likelihood of paradoxically agitated reactions to benzodiazepines [166]. Aggression is a more common after-effect of treatment with benzodiazepines than is regularly noted [167], and it may be more likely in those with high trait anxiety at baseline and those with antisocial personality disorder [166]. Atypical antipsychotic medications have the best evidence for achieving

desired effects of reduced anxiety and aggression in patients with Cluster B personality disorders while avoiding adverse physical and mood reactions [168–170]. These agents may be valuable adjuncts in the critical care phase of treatment of DSP patients, as such personality pathology is common in those who take purposeful overdoses (Level II-3 recommendation).

Legal and Ethical Issues

Psychopathology and the circumstances surrounding many acute toxicology cases give rise to unique legal concerns and produce moral distress in caregivers. The central goal should always be the best care of the patient, defined by professional standards of medicine and the ethics of care relationships. Legal standards sometimes support and other times impinge on ethical work in healthcare. By virtue of their specific training and experience with mental illnesses that may rob patients of insight and decision-making capacity, C-L psychiatrists can be helpful sorting out the proper course of action in the care of toxicology patients whose cases may be complicated in these ways. Familiarity with laws governing involuntary treatment is critical to psychiatric practice, as are expertise in assessing capacity for medical decision-making and the ability to mediate strained interpersonal interactions between and among patients, families, and treatment providers.

Consent to treatment requires that a patient understands the risks and benefits of proposed treatment and those of alternative treatments, including the option of no treatment [171]. Adult patients are presumed to be legally competent, and competent patients should give informed consent for *any* specific treatment; when a patient is deemed incompetent, an appointed guardian may give consent. A central issue is that many critically poisoned patients present for care with delirium that interferes with communication, information sharing, and the consent process. In this situation, presuming that patients would not want care simply on the basis of suspected DSP

and withholding treatment would be to err in at least two serious ways: (1) discounting the role of potentially treatable mental illness underlying the “suicidal” poisoning event and (2) disallowing the possibility that a patient’s perspective on living and dying may have changed. (Level III recommendation) The majority of patients with DSP do have psychiatric conditions driving suicidality that are amenable to intervention [46, 172] and do not frequently object to being treated or to having survived [24]. In the interest of survival, when a medical emergency exists in a delirious DSP patient, treatment may be delivered under the common law of implied consent [173]. (Level II-3 recommendation) In addition, there is the common-law principle of a duty of care to consider. Not all countries or provinces have an English common-law tradition. However, in those that do have such a tradition, a duty exists when a physician undertakes the care of a patient such that the physician must exercise a standard of care that would minimize risk of injury to the patient. The standard of care to be expected is that of a “reasonable person” possessing the special skills and knowledge of the professional involved [174].

The problem of adequately caring for patients with a variable degree of suicidal intent; patients who present with a deliberate, toxicologically serious poisoning requiring specific interventions; and patients who refuse to accept treatment is still a recurrent clinical and legal dilemma facing clinicians. Staff can be immobilized by the threat of litigation – of being found negligent for failing to treat a patient in need of but refusing treatment – or of assault – for treating a patient without consent. The available advice on how to proceed can seem conflicting. Legislation and common law may vary in different jurisdictions, and a clinician’s capacity to navigate the legal complexities may be inadequate. Treatment models that use psychiatric consultants and other staff or relatives to shore up the rationale for intervention and/or improve compliance with procedures may be useful to resolve conflicts [26]. (Level III recommendation) It is important to understand certain legal principles and precedents when determining an

approach to the treatment of a poisoned patient. A detailed examination of the clinical and legal standards for the care of suicidal patients in the United States is available [175].

One critical point to remember is that in medical emergencies, lifesaving care frequently proceeds without patients being aware or sufficiently cognizant of their circumstances to make decisions about what is done to or for them [176]. Although the patient's own actions (through DSP or drug misadventure) may be viewed as the cause of the toxicologic emergency at hand, the condition is still often just as critical, so as in other emergency situations in which lifesaving measures must be employed, physicians may institute treatment immediately without fear of incurring legal liability [171]. (Level II-3 recommendation) A review of the law in relation to suicide suggested that "it appears that there is a judicial assumption that there is a duty to take reasonable steps to prevent the suicide of a competent, informal (voluntary) patient in both psychiatric and ordinary health care settings" [177]. The common law recognizes that a reasonable person would want to receive treatment in a true medical emergency, even if his impaired awareness at the time of the emergency precludes giving informed consent. Practically this doctrine holds that the physician cannot be found legally liable for performing a procedure to which the patient has not consented, provided the situation is truly an emergency and the treatment itself is medically sound [173]. In most cases of drug misadventure, accidental poisoning, or unintended medication-related calamity, the forensic and philosophical calculus will be considerably less fraught due to decreasing levels of autonomous expression of lethal intent. Some cases are, of course, unclear and may have features suggesting a variety of causes and motivations behind the acute toxicologic presentation. Based on the logic, above, however, legal action taken against healthcare providers who intervene in the wake of self-poisoning rarely gains traction [178]. In this way, despite the potentially jarring and frustrating experience of caring for patient who is critically ill by his own hand, legal and ethical principles typically align in the majority of cases.

A degree of legal and ethical complexity does arise in rare cases when a patient with clear sensorium, who at least has the appearance of being a capacitated decision maker, actively resists lifesaving intervention. Examples include the relatively early presentation to hospital after ingestion of acetaminophen, lithium, warfarin, calcium channel blockers, and other potentially lethal agents with delayed impact on CNS function. An article from the United Kingdom outlining legal issues affecting the care of DSH patients emphasized the concept of competency as the principal determining factor in decisions concerning treatment; however, such a narrow "rights"-based view of competency in suicidal patients has been challenged in a review of case law in relation to suicidal actions [177]. It also has been suggested that because competency is a legal and not a clinical construct, clinicians are unable to apply such principles correctly [179]. Others have suggested that particular clinicians (e.g., psychiatrists) might be able to render an opinion as to a patient's competency and that psychiatrists are able to detect subtle forms of incompetency more readily than other physicians [171, 180, 181]. Although competency assessments usually involve cognitive criteria and processes, affective disorders [171, 182], paranoid states, and even anorexia nervosa also may affect a patient's competency [181]. Still, a medical opinion will be rendered about *capacity* for medical decision-making not *competency*. The former depends on the ability to understand one's condition, appreciate the consequences of various treatment options, weigh risks and benefits of each in a rational manner in light of one's goals and values, and make a consistent choice for a particular course of action [183]. Determination of capacity is always made for a particular decision or set of healthcare circumstances, whereas competency is judged as a more general state of ability for autonomous self-governance. Despite this distinction, courts do typically rule on a patient's competency in line with physicians' (especially psychiatrists') opinions on capacity [184].

The practical problem for a critical care toxicologist is the time it takes for such processes to render a guiding verdict. So, urgent psychiatric

consultation can be useful, but the backing of a judge will not come in time to allow delay of decision-making about lifesaving interventions. As a result, many toxicologists feel comfortable proceeding with a plan that entails compelling a patient to submit to care – a process that may involve physical restraints and forced medications – with or without the supporting input of a consultative psychiatrist. In such cases it is important to make a genuine assessment of the level of medical emergency involved to justify aggressive intervention. (Level II-3 recommendation) Self monitoring on the part of caregivers is also essential to avoid acting on the frustration engendered by resistant patients in ways that punish them or cause even more suffering – examples include the delivery of *N*-acetylcysteine in oral form when intravenous treatment would be adequate and more humane or the maintenance of physical restraints when pharmacologic treatment for agitation would provide relief and allow unbinding. Maintaining attention to patients' perspectives and experiences while navigating care relationships and crafting a treatment plan is advised. (Level III recommendation) It is useful to remember that many DSP attempts are carried out by individuals who feel as though their life events and emotions are both out of control and ingestions may, in part, represent a desperate attempt at mastery over them [185]. A purposeful ingestion may feel like the last available option to address overwhelming upset. Thus, taking away all control in the experience of toxicologic treatment can increase emotional distress and produce even greater conflict with caregivers. Preservation of a sense of autonomy with options, guided by psychiatric consultants if necessary, can more smoothly persuade ambivalent, distressed patients to accept lifesaving care (Level III recommendation).

Although rare, it is likely that a growing minority of patients will come to care with adamant resistance to treatment that is not merely a reflection of psychiatric distress. Most will not have sufficiently preserved CNS function to voice it in the moment, but they will have clearly articulated a desire to die in the context of sustained healthcare relationships. A relational,

contemplated, and consistently communicated desire for death is a key distinguishing factor in such cases. It is a core requirement in legally permitted pursuit of assisted suicide [186, 187], and it also supports the acceptable practice of foregoing life-sustaining interventions in terminal conditions like end stage renal disease and amyotrophic lateral sclerosis [188]. Still, in order to allow a critically ill patient to expire after deliberate poisoning, a physician cast in the caregiving role would have to be certain not only of intent but also of legality in the relevant jurisdiction. (Level III recommendation) Timetables of intervention in emergency departments and ICUs rarely allow for the necessary gathering of data. Ethical distress is virtually inevitable on some level for some portion of a medical team facing such a situation. The few cases documented thus far have been challenging and each unique in their own ways [189]. Not surprisingly, emotionally charged disagreements between and among family members can complicate matters, even though individual patient autonomy is the most prized bioethical principle in Western medicine, and assisted suicide laws are designed to enhance and defend it above other interests [190]. Urgent psychiatric consultation and, if available, medical ethics consultation are strongly advised to guide the course of action in these cases. (Level II-3 recommendation) It is also advised that hospitals make advanced preparations for how cases like these will be handled in light of local legal standards and practice guidelines crafted with input from the communities they serve (Level III recommendation).

One last category of even more complicated cases has recently highlighted the thorny convergence of these issues. For a number of years, advocates for better healthcare practices have encouraged patients to have proactive conversations with loved ones and treatment providers to outline wishes for interventions in various scenarios, particularly at the end of life. In the United States, the Physician Orders for Life-Sustaining Treatment (POLST) form is one common example of a simple document that comes out of such conversations and fairly informally guides providers within the health system in which it was

created [191]. Other patients have a clearly written, more legally binding set of advance directives. Patients with different kinds of healthcare documents have presented to acute toxicologic care with varying, unclear degrees of suicidal intent [192–194]. Intensivists have been reluctant either to honor or to ignore such directives when toxicology patients are critically ill. Some documents plainly state a desire not to be intubated or receive hemodialysis without qualification; despite that clear language, often the circumstances imagined that drive those firm written choices are those around terminal conditions in which such procedures merely prolong bodily integrity without the hope of restored health and function. However, intubation and hemodialysis have circumscribed utility that can prevent morbidity and mortality in cases of poisoning. Patients may be restored to full health with resuscitative care that must be instituted rapidly but is crucial to maintain for only a short time. Based on this rationale, and supported by precedent [195], some medical toxicologists are therefore more comfortable with overriding advance directives than with effectively participating in a patient's suicide plan that would be facilitated by such documents. This position is supported by a key analysis in the bioethics literature that recommends caution, consensus building, and the passage of time while critical care is maintained to gather data before considering the withdrawal of support – and considering withdrawal only if the same would be done in a case without suicidal overlay [196] (Level III recommendation).

At least one case has been published about a mentally ill individual who apparently crafted advance directives just days before an episode of DSP for the explicit purpose of making suicide completion more likely [197]. The 26-year-old patient ingested ethylene glycol, called an ambulance, and presented to hospital with her own self-prepared document in hand; she indicated that she desired to die on her own terms and insisted on comfort measures only. Despite longstanding depression and “untreatable” personality disorder, the patient was judged to have capacity to make these decisions and allowed to expire. The presence of interpersonal dysfunction tied directly to

the suicidal act and the absence of a legal sanction for assisted suicide in this case, however, would have led most psychiatric consultants to advise pursuit of all necessary lifesaving interventions. It is important not to merely assume that a suicide attempt automatically invalidates all advance directives, but following mandates of the most updated ethical analysis of the issues would lead to the same conclusion [198]. (Level III recommendation) As debates surrounding death with dignity evolve, POLST and other forms appear in the medical records of patients lacking capacity, and the threat of malpractice looms, the work of a critical care toxicologist in this arena will expand in complexity.

Vulnerable Populations

The majority of acute toxicology patients are young to middle-aged adults, but poisonings in other age groups are not uncommon. Unique issues accompany individuals at the extremes of age with which a psychiatric perspective can be helpful.

Adolescents and Children

Poisonings in young children, whether toxicologically significant or not, usually are “accidental,” in the sense of there being no deliberate intent on the part of the child to harm himself or herself. Most primary prevention programs aim to reduce the morbidity and mortality of these poisonings through educational initiatives and packaging modifications (e.g., child-resistant closures on containers of sublethal total doses). It has been suggested, however, that the factor most closely associated with childhood poisoning is the general level of psychological adjustment in the child and the family [199]. Perhaps 25% of all child patients repeat self-poisoning, and although few studies have focused on these populations, it would seem that child behavioral disturbance and family dysfunction are highly relevant [199]. In a series of clonidine poisonings reported in Australia, it was noted that the child's own

medication, for the treatment of a behavioral disorder, was the source of ingested medication [61]. There is a suggestion that rates of suicide attempt are increasing in younger children, especially those with mental illness and behavior disorders who are treated pharmacologically [200]. These findings suggest that psychiatric assessment in cases of all childhood poisoning cases may be worthwhile to identify possible remedial factors. (Level II-3 recommendation) We are not aware, however, of any consultation psychiatry studies or programs specifically directed at this population, and psychiatrists trained to care for children are often not available for acute hospital consultation.

Adolescent suicide, DSH, and DSP have been reported to be increasing in recent years [200, 201]. Drug and alcohol misuse has always been a major issue in adolescents, and increasing numbers of latency-aged children with recreational drug exposure resulting in treatment are being reported [202]. The assessment of the adolescent poisoned patient may present particular difficulties; staff from the psychiatric service may be able to provide consultation services for the patient and liaison services for the family and staff [122]. Psychiatric disorders are as common in child and adolescent suicide attempters as they are in adult patients, although the pattern of illness is different [203–206]. In addition to psychiatric disorders, self-poisoning patients frequently have difficulties in relationships with parents, boyfriends or girlfriends, school, work, or physical health [207]. Within the hospital setting, health professionals caring for children experience clinical and ethical problems similar to those of professionals involved in the care of poisoned adults, with some additional complexity. Parental psychopathology and relational conflicts with their adolescent children can stymie treatment plans. Assessment and care of the adolescent patient can be complicated by law. While parents and guardians remain the decision-makers for treatment (as long as they are deemed to have both capacity and the best interests of their children at the fore), many states enforce confidentiality in the substance use related care of teenagers [208, 209]. At the same time, work in psychotherapy with young people may

leave parents out of the details of the treatment, but suicidal risk is the recognized threshold for bringing in responsible adults [210]. The critical care of poisoned adolescents obviously can give rise to a complex mix of concerns along these lines. Staff from a psychiatric service may be able to address such difficulties, assisting with care relationships and legal logistics [122].

Delirium in children is often drug induced and is usually the result of accidental poisoning but occasionally may be deliberate or iatrogenic. Young age is a risk for unexpected and paradoxical reactions to compounds that affect the CNS [64]. A delirious child may interfere with intravenous lines and endotracheal tubes or even exhibit hostile behavior, and the psychiatric assessment and care of children at an early stage in delirium is recommended [211]. (Level III recommendation) Even when their ingestions are not intentional, children are often at risk for acute and chronic problems with adjustment after a poisoning event [212, 213]. In the ICU in particular, the presence of a parent may be one of the most useful interventions for reassurance and behavioral management [214] (Level III recommendation).

Other clinical scenarios with focus on parents require mention. Although uncommon, children are vulnerable to being victims of poisoning, and the responsible party in the majority of these cases is a parent. Sometimes the intent is not to cause harm but to exert behavioral control. In either case, however, protective services for the child (and any siblings) should be pursued. (Level II-3 recommendation) Some unfortunate situations may result from severe mood and psychotic illness in a parent, so psychiatric consultation may be indicated. Munchausen syndrome by proxy is a form of factitious disorder in which an adult presents another vulnerable individual (usually a child) for hospital treatment. The child may be gravely ill, particularly if a poisoning has engendered the clinical presentation [215]. Parental motivation is typically to receive attention as the attendant to the child, therefore interacting with caregivers in deceitful ways that obscure the true cause of sickness and prolong episodes of care is common [216]. A poisoning in this context is particularly stressful and warrants psychiatric

involvement as part of a multidisciplinary approach [217]. (Level III recommendation) Legal intervention for the safety of the child may be necessary, and notification of child protection services is mandatory. Considering the severe psychopathology in such parents (often in the form of Cluster B personality disorders), mental health intervention to prevent a reactive act of violence or self-injury may be required. Child and parental deaths have been known to occur in this curious syndrome.

Elderly Patients

Baseline cognitive deficits are the greatest source of toxicologic vulnerability in older individuals [113]. As already noted, medications that impact CNS function have a greater likelihood of serious consequences in those who already have neurologic impairment. The elderly also take more medications at the same time that diminished hepatic and renal function reduce clearance of those potential toxins. Medication errors at home in those with failing memory and/or eyesight are a major problem. As in the case of children, involvement with mental health services in the wake of a toxic event can help to reveal underlying problems in the individual and his psychosocial system to prevent recurrence. (Level II-3 recommendation) Studies have shown that psychiatric consultation in the acute medical setting is one of the most common methods by which dementias come to light in a way that leads to necessary outpatient interventions, so it is part of standard practice for psychiatrists to assess carefully for cognitive disorders in hospital consultations [218]. Even during the course of acute treatment, C-L psychiatry can help with strategies to prevent complications from delirium and manage expectations for CNS recovery (which takes longer in those of advanced age). (Level III recommendation) An episode of delirium comes with increased risk of cognitive impairment several months after hospital discharge in any patient [219], with older patients having a greater likelihood of not returning to premorbid mental functioning [54, 163].

Physical limitations add complexity to life circumstances in the elderly, as well, with dependence on caregivers and more general reliance on goodwill. This makes older patients with less resilience and independence more likely to suffer toxicologic problems at the hands of others. Patients of all ages with physical and intellectual disabilities are vulnerable in similar ways and are thus at elevated risk for abuse and neglect perpetrated by those charged with their care – a situation for which a toxic exposure may be the heralding event. The literature outlines in sad detail how the cognitively and physically challenged suffer abuse in professional care settings of various types, and an important proportion of those events is mediated by toxic exposures [220–222]. The elderly may be the most frequent victims of homicide by poisoning [223], but psychoactive substances can be used with malicious intent (e.g., sexual molestation, assault, robbery, abduction, and attempted murder) toward vulnerable individuals in any age group. History taking from multiple sources with an open but critical appraisal of information is essential to revealing the psychopathology behind such rare toxicological presentations. With their focus on detailed evaluation of relationships and systems surrounding an identified patient, psychiatrists may be instrumental in uncovering foul play.

Lastly, the problem of elder suicide is an important reason for presentation to critical toxicologic care. Mortality after suicide attempt is common in older individuals, with frequent use of lethal means, so a smaller fraction of elderly attempters reaches hospitals (Fig. 1). Those who do and survive demand special attention. DSP represents an opportunity to intervene in this portion of the population with the highest suicide rates [201]. Psychiatric consultation is a must in any older person presenting for acute hospital treatment who raises concern for suicidality, despite the fact that resistance to mental health care is common in this age group. (Level II-3 recommendation) The elderly may also receive psychiatric consultation at lower rates than younger patients due to physician biases [224]. However, identification of treatable mental illness in older people with interventions focused on safety – like mobilization of care relationships

and restriction of lethal means – is essential. Acute psychiatric hospitalization may be necessary, as well, but attention to other risk factors common to this group (e.g., pain, chronic physical illness and disability, isolation, loneliness) is even more critical to prevent an episode of DSP from being the sentinel event on a path to eventual suicide [225, 226] (Level II-2 recommendation).

Psychosomatic Interventions and Outcomes

Of the range of potential outcomes of DSP, there are three that are most important to discuss here: psychiatric treatment, repetition of poisoning, and subsequent suicide. Psychiatrists should have interest and a potential role in individual patient care along with public health initiatives around each of them. Psychiatric care also is important in other circumstances involving poisoned patients. Chronic neuropsychiatric sequelae sometimes can follow serious poisonings (e.g., with agents such as carbon monoxide [227] and organophosphates [228]). Patients with chronic illness states arguably attributable to various toxicities [229], such as “multiple chemical sensitivity” [230], also may benefit from psychiatric input to reframe expectations and plan a recovery-based model of care to restore function [231]. (Level II-3 recommendation) Occasionally an anxious or psychotic patient, believing himself or herself to be seriously poisoned, may enter the treatment system as a toxicology patient and present a clinical challenge [105]. Some chronic poisonings (e.g., carbon monoxide, lead, and mercury) may present with primarily psychiatric symptoms [232], and recognition of the toxicity may be delayed. A discussion of these specific examples is beyond the scope of this chapter.

Psychiatric Treatment

Psychiatric hospitalization may be the next intervention after physical recovery from an acute episode of DSP. It is common practice to keep patients under close observation, in opposition to

their desire to leave the hospital if necessary, until psychiatric consultation can be obtained to assess for safety and treatment needs. If an individual remains acutely suicidal, the required medical setting needs to be a secure environment with close observation. (Level III recommendation) A patient whose intentional ingestion does not result in a substantial change in mental status and/or level of consciousness may be at higher risk due to ongoing self-injurious urges from unmodulated psychiatric distress [24]. However, the vast majority of patients who experience delirium or coma from DSP do not have ongoing suicidal upset after recovery of CNS function [24]. For this reason (along with the reality of decreasing availability of inpatient psychiatric beds, at least in the United States), a growing percentage of DSP patients are not treated with the decades-old British Atkins Report recommendation for universal psychiatric hospitalization [233]. (Level II-2 recommendation) When mental health hospitalization is planned that involves transfer to an appropriate treatment center, patients’ somatic medical needs must be considered. As many facilities are now no longer connected to general hospitals, but free-standing (with little in the way of acute medical support), there may be some resistance to accepting patients for care who have physical treatment needs – or even benign laboratory abnormalities. A recent severe poisoning can raise concerns for receiving providers, as well, therefore having psychosomatic medical experts consulting on such cases can provide the necessary liaison for more efficient transfer to the next phase of care (Level III recommendation).

Mental health expertise can be helpful in determining the best use of care resources in the wake of DSP, drug misadventures, and toxicologic accidents, taking into account the specific factors involved in the acute presentation of each case in conjunction with the chronic conditions underlying them. Historically, the very act of DSP sufficient to require critical care led some psychiatric consultants to almost reflexively opine that judgment is impaired, risk is high, and the individual in question must be ill. Over time, however, psychosomatic medicine experts have emphasized looking beyond the severity of the poisoning

event to evaluate an individual's foregoing and subsequent states of mental health to determine what issues are amenable to intervention and in what form and setting [234]. (Level III recommendation) Psychiatric disorders [16], substance-related problems [235], and personality disorders in adults [21, 236, 237] and adolescents [238] are common in populations of DSP patients, although the patterns of illness may be different at different centers [46, 239]. In the absence of randomized controlled trials to clearly indicate which patients with which conditions should be psychiatrically hospitalized after DSP, studies of cohorts of patients suggest that the choice should depend on clinical factors psychiatrists use to determine the necessary level of care for other patients seen in acute consultation [234]. (Level II-2 recommendation) Hospitalization most commonly is instigated to protect a patient from imminent risk of self-harm, to reduce the risk of harm to others, to treat a psychiatric disorder or personality disorder, or for a combination of these reasons. It should always reflect a plan to address a condition that may be treated rather than a mere concern for the possibility of repeat suicidal behavior. (Level III recommendation) Following this principle may lead to a decision against admission of some DSP patients, and conversely an acute toxic episode may herald serious mental illness acuity that demands inpatient treatment even if the exposure was not deliberate or suicidal. Persisting psychotic symptoms or mood disturbance after a drug misadventure could also warrant inpatient mental health intervention. Not surprisingly, then, the rates of psychiatric admission directly after poisoning episodes are unclear and locally variable – for DSH, a range of 5–10% has been reported in the United Kingdom [16], whereas another study reported a rate of 28% in a US unit [19], and a Swedish study found a rate of 57% [240]. A study restricted to DSP patients in Australia reported 29% referred for psychiatric hospitalization, 18.3% on involuntary status [241]. It is to be hoped that because the majority of DSP patients frequently have a psychiatric disorder, have psychiatric symptoms, or at least are making a “cry for help,” appropriate aftercare can be provided. Studies of depressed and alcohol-

dependent patients who have made a suicide attempt suggest, however, that treatment before and after a suicide attempt is frequently inadequate [242, 243]. Attendance for psychiatric follow-up when offered after a poisoning episode has been reported to be as low as 16% [244]. A majority of adult victims of DSP have not historically made durable, sustaining connections to mental health services. Unfortunately, the same is true for young people who should, presumably, have invested family members involved to advocate and ensure participation in treatment [245, 246]. Important elements of care may include addressing potential sources of nonadherence, determining proper intensity of treatment, providing family psychoeducation, treating concurrent psychopathology, and remediating social skills and problem-solving deficits [247], all areas of expertise offered by a C-L psychiatrist (Level II-2 recommendation).

Impaired insight and associated effects on treatment adherence are a *sine qua non* of mental illness. However, the issue of coercion may play a role in patients' low rates of consistent follow-up after DSP and drug misadventures as well. Psychiatric hospitalization may be undertaken under voluntary or involuntary status. Even patients who voluntarily enter acute mental health treatment report experiencing a sense of coercion [248]. Study results are mixed, but being coerced into treatment as opposed to receiving clear communication of clinical rationale with fair assignment of voluntary versus involuntary status at the time of admission may be associated with poorer outcomes in the form of symptom change [249] and in maintenance of connection to mental health resources [250, 251] – particularly in patients from minority and disadvantaged backgrounds [252]. For this reason, clear communication in line with reasoned clinical assessment is superior to “bargaining” from a position of authority about admission versus discharge. (Level III recommendation) Issues around power and decision-making in care relationships can be challenging to navigate when balancing autonomy and beneficence, but it is recommended that sensitivity to these issues be maintained with the patient's best interest at the fore as disposition after critical

toxicologic care is planned [253]. The ethical values of law and medicine may come into conflict when the possibility of involuntary psychiatric treatment is concerned [254]. However, in the treatment of psychiatrically ill patients, initial imposition on autonomy can lead to greater freedom [254]; in other words, a greater benefit may accrue to the patient because of the insistence on legally applying appropriate psychiatric treatment.

For a patient with ongoing psychiatric acuity, accompanying imminent suicidal risk is a central issue when it comes to pursuing hospitalization even when the individual would prefer otherwise (v.i.). In a review of treatment standards for patients at risk of suicide in the United States, the authors noted that reasonable care must be shown by certain affirmative precautions, with standards equivalent to those prevailing in the community, and that the duty of care is proportionate to the patient's needs [255]. The most common legal action brought against psychiatrists is for the failure to protect patients from harming themselves, and courts impose much stricter standards on inpatient than on outpatient care [255]. Psychiatrists who follow the procedures of civil commitment laws are likely to have a broad protection from liability [256]. Patients who are willing to have acute psychiatric care after DSP may be disposed of by their medical teams to mental health facilities without such expertise from C-L psychiatry. But, having psychiatric consultants involved in all cases where there are conflicts between perspectives of care teams and patients regarding disposition can help to navigate the legal process effectively for critical care providers as well (Level III recommendation).

Specific legislation usually defines the circumstances in which a person may be detained involuntarily. Details vary among jurisdictions but typically the patient must be both "mentally ill" and dangerous to either self or others. This judgment involves a prediction concerning the likelihood of such dangerousness or harm and an accepted threshold for such a prediction [253]. The clinical task often involves an evaluation of the balance between civil liberty and

enforced protection and benevolence [257]. Some authors have suggested that the complexity of such evaluations, lack of reliable community psychosocial services, and fear of litigation from other parties down the line (e.g., family, victims of violence) may lead to some patients' being unnecessarily hospitalized under civil commitment justified by a perceived risk of violence [258, 259].

In 1983, "a model state law on civil commitment of the mentally ill" was proposed in the United States, suggesting four criteria necessary for involuntary commitment [260]. A later summary of commitment legislation suggested six common criteria (Table 2), which essentially still obtain [261]. An important focus of these developments was the need to place the patient's interests first, especially the need to address psychiatric conditions likely to respond to treatment and not to consider potential dangerousness as the only criterion for commitment [260]. (Level II-3 recommendation) Similar principles have been incorporated into mental health legislation in other countries [262–264]. In a review of all statutory requirements for involuntary hospitalization in the United States, it was found that each jurisdiction requires a person to have a mental illness and be dangerous to himself or herself, and 85% of jurisdictions require the dangerousness to be a result of the mental illness [265]. Only two jurisdictions require, however, that an attempt be made to involuntarily commit a person in imminent danger to himself or herself. These findings were similar to an older review [266].

Table 2 Eligibility for involuntary hospitalization from two studies

Stromberg and Stone [260]	Bednar et al. [261]
A severe mental disorder is present	Mental illness
Lacks the capacity to make a reasoned treatment decision	Danger to self or others or grave disability
Has a treatable condition	Refusal to consent
Likely to harm self or others	Treatable condition Lack of capacity to decide on treatment Use of the least restrictive treatment

It has been suggested that clinicians rely particularly on the “dangerousness” criterion in seeking a commitment while being sensitive to the patient’s need for treatment [267]. Noting the limitations of predicting imminently dangerous behavior in individuals and the rarity of completed suicide in general, more recent work in forensic psychiatry recommends a focus on respect and supports the right of persons to make decisions, rather than on perceived vulnerabilities and calculations of suicide risk [268]. (Level III recommendation) In the care of children or incompetent adults, parents, legally appointed guardians, or other responsible individuals serve as decision-makers with respect to treatment, so psychiatric hospitalization may be pursued voluntarily even if a patient does not assent. Rarely, it may be necessary to pursue involuntary treatment against the will of a parent or legal guardian on the basis of acutely dangerous mental illness. In general, however, the younger the patient, the less likely an inpatient psychiatric admission will be necessary or helpful, and the more likely a consultant will determine that ongoing safety can be assured by family and/or caregivers at home with guidance, where some interventions can take place alongside intensive outpatient programming (Level II-3 recommendation).

In recent decades, partly to address shrinking availability of inpatient mental health beds, a number of treatment programs have been created that can serve as a sufficient match for different levels of psychiatric acuity. Table 3 lists various forms of mental health care that may be pursued as an appropriate level of support after episodes of toxicologic critical illness. The recommended choice will generally depend upon an assessed risk of violence and/or self-harm with corresponding need for safety monitoring in conjunction with suitability of specific treatment offerings for a particular patient. Some individuals have conditions that may be expected to stabilize quickly, whereas others may be deemed to require longer-term treatment before being safe to return to care in the community. For others, a significant (even primary) focus on chemical dependency may be the key to recovery. Inevitably, some options will not be available in certain locales,

Table 3 Mental health treatment options after toxicologic care^a

1. Highest acuity locked facilities
a. State-sponsored long-term residential treatment program
b. Inpatient mental illness and/or chemical dependency program ^b
c. Acute crisis-stabilizing inpatient psychiatric unit
2. High acuity unlocked facilities
a. Intensive residential treatment program
b. Acute/residential chemical dependency program
c. Sub-acute stabilizing inpatient program ^c
3. Moderate acuity resources
a. Partial hospitalization program (“day treatment”) ^d
b. Intensive outpatient program
c. Community-based crisis housing program
4. Low acuity resources
a. Monitored/supportive residential placement
b. Assertive community treatment (ACT)
c. Structured group therapy program (e.g., dialectical behavior therapy)
d. Urgent access clinics
1. Psychopharmacology
2. Psychotherapy
3. Social services/intensive case management
e. Continuation of established outpatient treatment

^aMental health care resources are presented in decreasing level of acuity and corresponding capability of active safety monitoring. Within each numbered group, options are listed in decreasing order of resource intensity with a generally inverse relationship to the time necessary for placement in a given program

^bPrograms that combine treatment for addictions with other mental illnesses (i.e., MCD programs) are less commonly available but may offer better care of patients with these comorbid conditions

^cSome inpatient units are unlocked, but still offer a high level of intensive treatment. They are more common for particular illnesses and/or populations (e.g., primary mood disorders, eating disorders, adolescents)

^dPatients in partial hospitalization typically gather on units similar to inpatient settings for intensive treatment during most days of the week and return home each evening

and bed availability may also necessitate moving up or down from an initial recommended level of intervention; this unfortunate practical reality may be particularly relevant for patients at the extremes of age for whom a shortage of specialized services is the rule in most areas of the United States and United Kingdom, despite the appearance of growing demand [269–271].

As previously noted, an inpatient locked facility may indeed be necessary for a patient whose ongoing mental illness acuity is sufficiently high

to make further suicidal behavior imminently likely. Such units typically have a variety of services available (e.g., psychopharmacologic expertise, psychotherapy, and social services) and the ability to make detailed multidisciplinary assessments with referrals to ongoing care aimed at preventing recurrence of suicidal crises. Sometimes an inpatient stay makes for more efficient connection to long-term resources; hospitalization may even be required to meet eligibility for certain services. But patients may wait days or even weeks in some healthcare systems to access inpatient care. Having C-L Psychiatry actively involved to advocate for patients and their families can fulfill some requirements and, in some cases, expedite connection to services. Ongoing assessments can help to gauge when patients may safely transition to different levels of care that are available, as some patients who linger in hospital with sequelae of acute poisoning (e.g., receiving short-term hemodialysis until resolution of toxic renal failure) may be quite mentally stable once ready for medical discharge. Also, having C-L teams begin to deliver treatments after recovery from a poisoning event – first in the form of psychotherapy and when it is toxicologically safe, perhaps with medications as well – can help to stabilize mental illness and ready patients for disposition options other than acute psychiatric hospitalization.

Repeat Episodes of Poisoning

Much of the focus on the issue of psychiatric treatment relates to the hope that assertive after-care intervention will prevent recidivism. Repetition of DSH has been reported to have annual rates of 6–30% (median 16%) [16]. According to one Australian study, repeat DSP is quite common after an index medical encounter has ended; 4.5% of overdose patients present to hospital again within a month, 10% within 6 months, and 14% within a year [20]. It is not yet clear the extent to which particular models of service provision affect repetition rates. Hospital admission improves access to psychiatric services [26, 81], and studies suggest less favorable outcomes for

those discharged after emergency observation only [272, 273]. Therefore, admitting all DSP patients rather than making discharge decisions based on any of the complex analysis outlined above may have merit [16, 233, 274]. As previously discussed, however, such a practice policy is not clearly correlated with decreasing repeat DSP or suicide, is not in line with legal and ethical standards, nor is it feasible in most healthcare catchment areas (*vide supra*. Psychiatric Treatment). On the other hand, merely arranging for systematic follow-up with primary care medical providers after DSP is not sufficient to address mental illness acuity, reduce suicidality or hopelessness, or reduce rates of repeat attempts [275]. Therefore, efforts to provide for thorough psychiatric evaluation and treatment planning must be undertaken without reliance upon the option to transfer all DSP patients to an acute mental health facility. (Level II-2 recommendation) C-L Psychiatry presence in the acute medical setting may be helpful not only with that necessary evaluation but with making recommendations and arrangements for clinically meaningful interventions (Level III recommendation).

Certain DSP patients may be deemed suitable candidates for the few evidence-based interventions that may decrease the likelihood of repeating. In recent years, there have been a number of systematic reviews and meta-analyses reporting on interventions to prevent or reduce repetition of DSH. Although there have been no pharmacological interventions of clearly demonstrated effectiveness, there have been effective psychological and brief contact interventions for unselected adult hospital-treated DSH populations; effective psychological interventions for adults meeting diagnostic criteria for BPD; and effective psychological interventions for adolescent DSH populations. The two main outcomes of interest are: the binary outcome of any episode of repeat DSH and the number of repeat DSH events.

A recent Cochrane review of pharmacological interventions identified only seven relevant trials ($n = 546$ participants). There was no effect on any repeat DSH (including DSP) for: newer generation antidepressants, low-dose fluphenazine, mood stabilizers, or natural products. A

significant reduction in repetition of DSH was found in a single trial of flupenthixol (OR 0.09, 95% CI 0.02–0.50), although the quality of evidence was very low. There was no data available on adverse effects. Authors of the review concluded that it is not possible to make firm conclusions regarding pharmacological interventions because of the low quality of the available evidence and the small number of trials identified [276]. Specific focus on patients with the highest rates of repeat DSP/DSH has not been promising with respect to pharmacotherapy either. Meta-analysis of four trials of drug treatments showed that pharmacotherapy was ineffective in reducing repetition of DSH events in patients with BPD; while individual drug trials, valproate (one trial), olanzapine (two trials), and ziprasidone (one trial) also showed no benefit [277]. From the perspective of a medical toxicologist, especially noting these findings, reliance upon nonpharmacologic interventions for patients with high rates of DSP may be more prudent.

A recent systematic review of psychological and psychosocial interventions in unselected DSH populations identified 36 trials with suitable data available from 30. Meta-analysis showed a significant benefit for all psychological and psychosocial interventions combined for the outcome of any repeat DSH (RR 0.86; 95% CI 0.76–0.98), (NNT = 33) and significant effectiveness for the secondary outcomes of suicidal ideation severity, depressive symptoms, and hopelessness. For specific therapies, there was a statistically significant effect in favor of cognitive behavioral therapy (CBT) (4 trials: RR 0.80; 95% CI 0.66, 0.97) and a larger effect in favor of psychodynamic interpersonal psychotherapy (1 trial: RR 0.31; 95% CI 0.12, 0.78), (Level I recommendation) but no statistically significant effect for complex interventions with outreach, problem-solving interventions, or “other” interventions [278]. A recent systematic review of brief contact interventions without therapy (letters, postcards, electronic messages, and telephone calls) in unselected DSH patients identified 14 trials with suitable data available in 12. Brief contact interventions showed a nonsignificant reduction for any form of repeat self-harm (OR) 0.87; 95% CI

0.74–1.04) but a significant benefit for the number of repetitions per person (IRR = 0.66, 95% CI 0.54–0.80) [279]. (Level I recommendation) Thus, an episode of critical toxicologic care can provide an opportunity for meaningful intervention through a mechanism as simple as sending a postcard after discharge – a gesture whose impact may remain significant for a variety of DSP patients even years after an index self-poisoning event [280].

For the specific population of patients with a diagnosis of BPD, a recent clinical practice guideline has been published. These guidelines reported a meta-analysis of 10 trials of psychological treatments, which showed benefit in reducing the repetition of DSH events compared with treatment as usual. Five specific trials that showed a significant reduction in repeated DSH involved treatment with dialectical behavior therapy (DBT) [277]. This form of psychotherapy relies on principles of Eastern spiritual living in conjunction with skills training to cope with intensely disturbing emotions and urges [281]. It was created to address the inability of some personality disordered patients to benefit from a common treatment that focuses more narrowly on thoughts and actions that either perpetuate or aid recovery from mental illness – CBT. Mentalization based therapy (MBT) has a similar inspiration and purpose, focusing on understanding and managing mental processes and their impact on relationships between self and others [282]. Along with the thought-focused manual-assisted cognitive therapy (one trial), CBT (one trial) and MBT (one trial) were also associated with significant reductions in DSH events [277] (Level II-1 recommendation).

For the DSH population of children and adolescents, a recent Cochrane review identified 11 trials ($n = 1,126$ participants) all were psychosocial interventions. Only dialectical behavior therapy for adolescents (DBT-A) and group-based therapy had multiple trials, and all other interventions were reported in single trials. There was no data available on adverse effects. DBT-A was not effective for the binary outcome of any repeat DSH but was more effective than enhanced usual care for frequency of DSH events as well as

reductions in depression, hopelessness, and suicidal ideation. (Level I recommendation) Mentalization based therapy was effective for repetition of DSH based on the risk-taking and self-harm inventory, in a population with repeated DSH or personality disorder. (Level II-1 recommendation) Other interventions, group-based therapy, compliance enhancement, CBT, home-based family intervention and provision of an emergency card, were not effective for the binary outcome of any repeat DSH [283]. A recent systematic review restricted to adolescent populations identified 19 trials ($n = 2,176$ participants); only psychological and social interventions were identified and no pharmacological interventions. There was a significant beneficial effect for all therapies combined for any repeat DSH (28% vs. 33%), with the largest effect sizes for DBT, CBT, and MBT. The authors concluded that psychological therapies appear to be effective; however, independent replication of DBT, CBT, and MBT trials is a research priority [284]. Good outcomes in the longer term may be related in large part to improvements in home circumstances and in relationships with supportive and well-functioning adults [205].

It is critical to note that a basic level of structure and support fit to a particular patient's overall level of function is necessary to implement any of these specific evidence-based treatments. (Level III recommendation) This is the rationale for a number of the options listed in Table 3. Some patients simply will not abstain from DSH without fairly constant oversight in a structured setting. Others with severe and persistent mental illnesses (e.g., schizophrenia, bipolar disorder) may benefit from the support of a multidisciplinary assertive community treatment (ACT) team of providers to enhance overall functionality and prevent repeated hospitalizations [285]. Such facilities and teams can then help to increase adherence to protective treatments, including depot medications to prevent episodic illness decompensations and training like DBT to manage suicidal distress [286]. (Level II-3 recommendation) In and of themselves, these services may not specifically reduce DSP but serve a necessary function in the longitudinal care of mental illness and provide a

framework within which to deliver specific therapies outlined above.

Still, a significant minority of DSP patients will return with another episode of critical toxicologic illness. Repeaters may have a higher general burden of psychopathology [287], with greater co-occurrence of personality disorder, psychosis, traumatic brain injury, and/or early childhood disruption [288, 289]. A similar pattern of psychiatric and social problems is reported for adolescent repeaters [290]. Repetition also may constitute a behavioral response to stressful situations [21]. Psychiatric assessment of these patients seems warranted during repeat episodes to address psychological morbidity and current personal crises even when previous consultations may appear to have had no benefit, and an impact on subsequent suicidal behavior may appear unlikely. (Level III recommendation) A pattern of difficulty or a particular issue in need of intervention may be identified that was not evident during previous rounds of treatment. Furthermore, as implied above, patients may not receive an adequate level of care in a healthcare system short on resources until repeat episodes of acute distress and danger are documented and used to build a case for more intensive resource allocation. Although a potentially frustrating process for hospital based teams that deal with a stream of critical illness situations, advocacy of this type that takes the long view of patients' lives before and after ICU episodes of care is essential to prevent a subsequent episode from ending in death.

Suicide

Although most patients who come to medical care after an overdose survive a given DSP attempt, nearly 20% of Americans who die by their own hand do so by ingestion of toxic substances [291]. A review of 24 longitudinal cohort studies concluded that patients with an episode of DSH have a 1-year median rate of completed suicide of 1% (approximately 100 times the general population risk) [16], and the 5-year suicide mortality rate after an index episode of DSH is over 4%

[4]. Prospective longitudinal research suggests that mortality rates specific to suicide in those with an episode of DSP are over 10% within 10 years [292]. The suicide risk is highest in the 12 months after an episode of DSH but remains substantially elevated over the general population risk for more than a decade [16]. About a quarter of all suicides are treated at a hospital for DSH in the year before they die, making the critical care toxicology unit an important point of opportunity in a serious public health epidemic [293, 294].

An exhaustive review of evidence-based suicide prevention is beyond the scope of this chapter. However, in the short term, during an episode of suicidal mood disorder, electroconvulsive therapy (ECT) has the best evidence to prevent loss of life [295]. (Level II-1 recommendation) After acute toxicologic recovery, psychiatric consultation will provide the most efficient path to treatment with ECT for suitable patients. Along with DBT (discussed above regarding evidence for preventing repeat DSH) [277], (Level II-2 recommendation) other evidence-based interventions are based on the long term. Particular medications like clozapine and lithium may decrease rates of suicide in high-risk populations with an “anti-suicide” effect that is independent of their impact on core symptoms of mental illness [296]. (Level II-2 recommendation) Since suicide is a relatively rare and largely unpredictable event that shows its public health impact over time in large populations, conducting studies to identify specific interventions that will prevent self-killing is challenging. For this reason, some experts have advocated a public health approach to the problem of DSP that seeks to shift the emphasis away from liberal use of psychopharmacology without evidence of benefit, minimize the availability of poisoning agents to patients at risk, and provide chemical dependency treatment to decrease unhealthy relationships with substances in general [24].

Collaborative Research Areas

The opportunities for future research at the toxicology/psychiatry interface are as limitless as the possibilities for scientific evaluation of antidotes

for specific poisonings. Some questions are more important because of their relevance to the seriously poisoned patient.

1. *What is the optimal pharmacologic management of delirium? Are there particular opportunities to optimize the management and care experience of acutely poisoned patients with delirium?*

There is a need for randomized controlled trials, with clearly defined populations, that evaluate drug and dosage regimens and use standardized instruments relevant to the core features of delirium or attendant behavioral disturbances to measure outcomes. More sophisticated work could be done through collaboration by crafting specific assessments and targeted interventions for different kinds of delirial states based on underlying etiologies and psychosomatic patient characteristics. Longitudinal studies are necessary to determine the impact of an episode of toxicologic critical care and its treatment on long-term psychosomatic health [297].

2. *What are the optimal pharmacologic treatments of the toxidromes – neuroleptic malignant syndrome, serotonin syndrome, and anticholinergic syndrome?*

There is a need for randomized controlled multicenter trials for definitive progress in the care of these specific conditions. Along with coordinating practical expertise, it may be necessary to develop suitable instruments to evaluate treatment response. Although these conditions are potentially lethal, study measures will need to address other outcomes in addition to mortality, since death is rare, but psychiatric and cognitive sequelae are common [110, 219]. A number of other clinically meaningful results for patients should be tracked, as well as resource utilization and lengths of hospital stay.

3. *Can repetition of deliberate self-poisoning be reduced?*

The repetition of DSP is an important phenomenon for which the epidemiology is reasonably well described, at least in some countries and regions. Now that systematic

reviews have revealed some potentially effective mental health interventions, practical attempts at larger scale implementation must be undertaken with meaningful assessments of success or failure. Other initiatives involving multidisciplinary collaboration could focus on reducing amounts of medications given with each prescription and purchase, and coupling delivery of new pills with pharmacy based take-backs of the old. The role of comorbid addiction must be investigated as well.

4. ***Which critically poisoned patients are referred for particular levels of psychiatric treatment; which patients benefit from hospitalization as opposed to other dispositions of care?***

These are important questions and, perhaps surprisingly, have not been addressed adequately. In a world of increasing use of pharmacologic agents in mentally ill patients and a corresponding decrease in hospital-based psychiatric care, the issue of resource utilization is critical. There are considerable limitations because of ethical constraints and practical difficulties in recruiting subjects. A fruitful approach would involve prospective, long-term, naturalistic cohort studies of clinical populations referred for psychiatric hospitalization. Outcome measures should include suicide, repeat DSP, service utilization, disability, quality of life, and social function.

5. ***What opportunities are available for medical toxicologists to improve outcomes in addictive disorders?***

Those involved in toxicologic critical care bear witness to the growing problem of morbidity and mortality from abusable substances, particularly alcohol, opioids, and synthetic stimulants. Studies are needed to identify potential interventions during and in the wake of an ICU admission for poisoning that may have a positive impact on chronic problems with substance misuse. A recent publication demonstrated that an episode of acute care after drug misadventure is an opportunity to reduce morbidity by limiting prescription of potentially lethal agents to those who are unable to regulate their use [298]. Research

should include attention to medications given, along with safety education for both patients and prescribers. As highlighted in a forward-thinking editorial piece, investigating opportunities for acute hospital contact to improve access to treatment for addictions and to implement harm reduction practices is a vital clinical science endeavor as well [299].

Future Interdisciplinary Developments

There have been calls by the US surgeon general for a systematic public health approach at a national level to reduce the frequency of suicide and suicidal behavior [300]. It also has been suggested that a comprehensive strategy aimed at preventing suicidal behavior should include a national collection of information on DSP/DSH and interventions, improved services for dealing with persons with suicidal behavior or at high risk for such behavior, the provision of information to and training of professionals and the public, and the provision of special services to high-risk groups [301]. In the United States, initiatives have been launched with focus on the problem of suicide in military personnel, specifically [302], and a taskforce to coordinate research with clinical practical applicability, in general [303], but neither has recruited medical toxicologists in any substantive way. Having experts in the care of poisoned patients actively involved in large-scale initiatives for preventing behavior that produces the majority of critical toxicologic illness is long overdue.

Furthermore, restriction of these interests only to suicidal or DSP patients would be misguided, noting the enormous public health problem of death and disability from addictive substances. Substance use disorders bring a growing number of patients to emergency and intensive care where a toxicologist may function as a part of a patient's network of addiction specialists, filling key gaps in access to expertise and coordinating with mental health providers to better integrate treatment for a variety of neurobiologically interrelated symptoms [304]. Safe and humane treatment of agitation is an important issue in both psychiatry

and toxicology. The related concerns of medical trauma and the accompanying critical issue of delirium for all hospitalized patients should also be of interest to both disciplines. Generally speaking, the large majority of individuals who come to the attention of a critical care toxicologist are likely to benefit from a mental health care perspective as well. There is ample opportunity for future collaboration between medical toxicologists and psychiatrists on many aspects of the management of poisoned patients and those who may have unhealthy relationships with exogenous substances.

It has been said that managing a pregnant patient involves managing two patients at once, the mother and the fetus. This dual management paradigm is often seen as a complex balancing act, benefits to the mother against risks to the fetus and vice versa. In the setting of poisoned patients, this takes on an even greater complexity, especially given the relative lack of literature to support or refute any given treatment recommendation. The higher acuity of the critically ill patient brings this situation to its sharpest point as the death of mother, fetus, or both becomes an ever more likely possibility. This chapter will discuss specific recommendations in greater detail, but as a general rule, the best approach to all poisoned pregnant patients is to treat the mother in the same way as if she were not pregnant. Improved maternal survival will typically lead to improved fetal survival.

As with other patients, poisoning in pregnancy can occur in several ways, including suicide attempt, and accidental exposures. Pregnancy adds additional concerns for poisonings more directly related to the fetus, namely exposure to abortifacients whether intentional by the mother or malicious by another person.

This chapter discusses poisoning in pregnancy in critically ill patients. Epidemiology, physiologic changes in pregnancy, gastrointestinal (GI) decontamination, general management, administration of antidotes, and abortifacients are discussed. Specific poisonings in pregnancy that are well described in the literature, some unique case reports, and the toxic effects of several obstetric medications are reviewed.

Epidemiology

In 2013, 7384 exposures in pregnant women were reported to US Poison Control Centers, representing 0.3% of all human exposures [1]. There were 31 pregnancy deaths reported to Poison Centers from 2000 through 2013; 27 of these were intentional. A 2012 survey estimated

that illicit drug use occurs in 5.9% of all pregnancies with higher rates in younger women [2]. In a study of nonnatural (homicide, suicide, accident, undetermined) deaths associated with pregnancy over a 6 year period, 52.5% had a positive toxicology report postmortem (includes caffeine), with drug toxicity as the cause of death in 13.2% [3].

A study through the Toxicology Investigators Consortium attempted to quantify the patterns of pregnant patients who are evaluated at the bedside by a toxicologist [4]. Of the 17,529 medical toxicology consultations recorded during the study period, 103 (0.6%) involved pregnant women. Of these, 88.7% involved pharmaceutical overdoses, 51.5% of which were intentional exposures. A total of 25.2% of these cases involved acetaminophen, followed by sedatives/hypnotics (18.4%) and opioids (16.5%). This study was limited in that it did not describe long-term pregnancy outcomes.

Most pregnant women who self-poison do so in the first trimester. According to a population-based prospective study by Czeizel and coworkers, 61% of suicide attempts occurred before completion of the first trimester. Many of these attempts (38%) were early in the first month, but most of these were in the third and fourth weeks [5]. The reported reasons for the suicide attempts were either unwanted pregnancies and related tension or crisis. Of the case study group, 22% had early fetal loss compared with pregnant women without overdose, matched by maternal and gestational age. Mortality was 0.36% in the study group compared with 0.0% in controls.

Knowledge of the outcome of these pregnancies after overdose is important because many of these women intend to harm the fetus. Flint and colleagues observed the results of pregnancy in 61 women who overdosed during pregnancy [6]. In this group, there was double the rate of miscarriages but no increased risk in congenital abnormalities or premature deliveries. Most of these women ingested acetaminophen, salicylates, psychotropics, or phenobarbital.

Teratology

Historically, the US Food and Drug Administration (FDA) has used a coding system for risk factors of possible teratogenicity to the fetus. Under this system, categories were assigned based on reliability of documentation and assessments of risks and benefits. As an example, category X (contraindicated in pregnancy) includes agents in which studies in humans or animals have demonstrated fetal abnormalities and/or there is a positive evidence of human fetal risk based on adverse reaction data from investigational or marketing experience and the risks involved in the use of the drug in pregnant women clearly outweighs potential benefits [7, 8] (Table 1). While it provides a simple reference point, the FDA categorization system has limitations and must be interpreted with caution. This is especially true of category C, which may indicate a paucity of data. Category C drugs can have animal data indicating abnormal fetal effects and

lack human data, or can lack both animal and human data. Unfortunately, in one study approximately 90% of drugs used in pregnancy were category C [8]. FDA pregnancy risk categories were assigned at the time a drug was approved by the FDA and rarely updated afterward. Similar systems are also in use in Sweden and Australia.

In December 2014, the FDA published a new Pregnancy and Lactation Labeling Rule which became effective in July 2015 [7]. This rule eliminates the letter categories described above in order to reduce confusion and improve the quality of information provided. The new labels will contain descriptive information on use of the medication in pregnancy (including labor and delivery), lactation, and in females and males of reproductive potential. Prescription drugs submitted to the FDA after the effective date will be required to use the new format, while older prescription drugs will be phased in gradually. The rule will not affect over-the-counter medications.

The fear of teratogenicity related to an acute drug overdose seems to be unwarranted in most cases according to two studies by Czeizel and colleagues [10, 11]. The first study evaluated 1399 cases over a 30-year period and found no increase in congenital abnormalities in women with a “semilethal” overdose, defined as patients who ingested an overdose amount sufficient to cause unconsciousness for 1 day [10]. A later study found no difference in teratogenicity in infants exposed to a drug overdose by the mother at 3–8 weeks of gestation [11]. Although the data are limited, it seems that the fetus in the “vulnerable phase” of 18–60 days of gestation either dies from the poisoning or survives without an increased risk for congenital abnormalities. These studies are based on a limited number of exposures; the potential for teratogenicity still must be considered for specific substances. This concern is further borne out by a later study by Petik and colleagues which showed an increased rate of mental retardation in children born after a maternal overdose on a combination insomnia treatment (amobarbital, glutethimide, and promethazine) but not with any of those drugs in isolation [12].

Chronic therapeutic use of pharmaceuticals more often will impact whether teratogenic effects

Table 1 Examples of drugs historically rated as pregnancy risk factor X by the US FDA

Amyl nitrite	Methotrexate
Atorvastatin	Methyltestosterone
Castor oil	Methysergide
Clomiphene	Mifepristone
Danazol	Misoprostol
Diethylstilbestrol	Oxymetholone
Ergotamine	Oxytocin
Estazolam	Podophyllum resin
Estrogens	Pravastatin
Conjugated	Prazepam
Esterified	Quazepam
Ethinyl estradiol	Quinine
Etretinate	Ribavirin
Finasteride	Simvastatin
Flurazepam	Stanozolol
Fluvastatin	Temazepam
Isoretinoin	Testosterone
Levonorgestrel	Thalidomide
Lorazepam	Thiethylperazine
Lovastatin	Triazolam
Megestrol acetate	Warfarin

Adapted from Leikin and Paloucek [9]

occur. The use of selective serotonin reuptake inhibitors (SSRIs) during pregnancy are a current example of drugs being studied for their adverse effects. A recent multicenter study in the United States examined the National Birth Defects Prevention Study database to identify infants with or without birth defects [13]. They correlated this with maternal use of SSRIs 1 month before pregnancy and during the first 3 months and found some SSRIs were not associated with birth defects, while fluoxetine and paroxetine were associated with 2–3.5 times greater chance of birth defects. An earlier meta-analysis of 115 studies similarly found fluoxetine and paroxetine at increased risk for major malformations (odds ratios 1.14 and 1.29, respectively), while sertraline and citalopram were not associated with an increase [14].

When abusing recreational drugs, such as cocaine or alcohol, the pregnant woman may not be trying intentionally to harm herself or the fetus, but she still is putting her fetus at risk of intrauterine growth retardation, premature delivery, fetal demise, placental abruption, and fetal alcohol syndrome [15]. It also has been shown that women with a positive screen for substances of abuse are at increased risk for being physically abused [16].

For concerns about exposure to teratogens in pregnancy, it is useful to consult a medical toxicologist or a teratogen information service, if available.

Physiology of Pregnancy

Maternal Physiologic Changes

The physiologic changes in pregnancy can result in maternal exposures to toxins that are different from those of nonpregnant women at the same dose (Table 2). Gastrointestinal absorption is changed significantly by pregnancy. The hormonal effects of pregnancy cause delayed gastric emptying, decreased GI motility, and prolonged transit time. These changes lead to delayed but more complete absorption. These physiologic changes theoretically may make attempts at gastric decontamination more efficacious in overdose

Table 2 Physiologic changes of pregnancy

General physiologic changes
↑Body mass 25% by term
↑Body water 7–8 L
↑Body fat 20%
↑Temperature 0.5 °C
Specific systems
<i>Cardiovascular</i>
↑Cardiac output begins by 6 weeks
↑Cardiac output 35% by 10 week
↑Cardiac output 48% by 25 weeks
↑Heart rate 20%
↑Stroke volume10–32%
↓Peripheral vascular resistance
↑Peripheral flow
↓Oxygen extraction
↑Oxygen consumption
↓Blood pressure by second trimester (10–15 mmHg diastolic, 5–10 mmHg systolic)
<i>Respiratory</i>
↑Arterial PO ₂ 10 mmHg
↓Arterial PCO ₂ 10 mmHg
↑Minute volume 40–50%
↑Respiratory rate 0–15%
↑Tidal volume 40%
Vital capacity baseline
↓Functional residual capacity 20%
↓Expiratory reserve volume 20%
↓Residual volume 20%
↓Airway resistance 36%
<i>Gastrointestinal</i>
↑Nausea and vomiting
↓Lower esophageal sphincter tone
↑Gastroesophageal reflux disease

during pregnancy. However, most studies in nonpregnant patients have not shown that attempts at GI decontamination in poisoned patients significantly affect their clinical course or outcome.

Because minute ventilation and tidal volume increase while residual capacity decreases, respiratory absorption of a poison can be increased in pregnancy. Inhalational exposures, such as those to carbon monoxide (CO), may be more serious in pregnant women because pregnant women also have less respiratory reserve to compensate for any respiratory insult.

The potential for dermal exposure is enhanced during pregnancy for two reasons. First, there is the increase in body surface area with increasing body mass and the gravid abdomen. Second, increased peripheral blood flow to the skin enhances the possibility of drug absorption. Neither of these changes has been definitively proven to be clinically relevant.

Toxicopharmacokinetics also changes during pregnancy. The volume of distribution of most substances increases because of the expanded plasma volume and body fat stores. The albumin level decreases and the cardiac output increases during pregnancy, allowing for more free drug to distribute to target organs, including the placenta.

Changes in serum pH at different times during pregnancy cause the ionization of some drugs, leading to changes in tissue penetration and elimination. Early in pregnancy, the fetal pH is elevated compared with the maternal pH. Weak acids, such as salicylates, phenobarbital, valproic acid (VPA), trimethadione, phenytoin, thalidomide, warfarin, and isotretinoin, pass through the placenta in an electrically neutral state, but in the relatively alkaline fetal fluids, they may become ion trapped [17]. Late in gestation, the fetus's blood becomes more acidic than the mother's, and weak bases likewise diffuse into and become trapped within the fetus.

Late in gestation, maternal free fatty acids increase, displacing protein-bound drugs, such as diazepam and VPA, from serum proteins [17]. This displacement results in potentially greater toxicity by reducing the natural "chelator" effect of these proteins. In contrast, the hyperdynamic state of the pregnant patient causes glomerular filtration rate increases, and more renally cleared substances potentially can be excreted in the urine.

Placental Factors

The placenta acts similar to an internal dialysis unit, which can increase or decrease the likelihood of fetal toxicity. It allows most drugs to pass by simple diffusion along the natural maternal-to-fetal concentration gradient. Substances weighing less than 1000 Da tend to have the capacity for passive diffusion across the placental membrane [18]. Drugs with small molecular weight, lipid solubility, neutral charge, and low protein binding are more apt to pass through the placenta. A common exception to this rule is iron, which enters the placenta by receptor-mediated endocytosis [19–21].

Another important exception to the aforementioned generalizations is acidic drugs such as valproic acid. These drugs are predominantly ionized at the mother's physiologic pH, but the small amount that remains nonpolar readily diffuses across the placental membrane [22]. The ionized and nonionized fractions tend to approach equilibrium in the maternal serum. The ionized fraction, which is made greater by placental removal of the nonionized, drives the equilibrium toward the neutral form in maternal serum. The latter can diffuse across the placenta. This maternal equilibrium process and the placental passive diffusion of the nonionized drug continue cycling, leading to enhanced concentrations in the fetal circulation.

Fetal Factors

The fetus has physiologic characteristics that can protect it from or make it more susceptible to the toxic effects of maternal poisoning. The fetal oxygen-hemoglobin dissociation curve lies to the left of the mother's [23]. This position allows the fetal hemoglobin to bind oxygen at a lower PO_2 . However, the hyperbolic shape of the fetal oxygen-hemoglobin curve also can be a disadvantage because fetal tissues are less able to extract oxygen from the hemoglobin. Also, because the curve is steep, a shift to the right because of acidemia results in decreased binding of fetal hemoglobin to oxygen at lower PO_2 .

The fetus also has a physiologic reflex response to hypoxia. This response consists of apnea, bradycardia, systolic hypertension, peripheral vasoconstriction, and lactate production. The vagally mediated response to hypoxia causes a direct negative inotropic response, which can be reversed with atropine. The peripheral vasoconstriction allows shunting of the blood to critical organs, such as the heart, brain, adrenals, and placenta. While beneficial for oxygenation, in a poisoned patient this reflex theoretically increases toxin delivery to vital tissues.

Treatment of Poisonings in Pregnancy

The same aggressive supportive care that one would render to a nonpregnant poisoned patient should be administered to a pregnant patient (Grade III). In general, if a toxin is causing seizures or hemodynamic instability in the mother, it also is having negative effects on the fetus. The optimal approach is to treat the mother; this is especially true in the critically poisoned patient. A remarkable report described a 27-year-old woman, 15 weeks pregnant, iatrogenically poisoned with intravenous lidocaine by the administration of a 1000-mg bolus (instead of 100 mg) for the treatment of bigeminy [23]. This patient developed multiple arrhythmias, including electromechanical dissociation, asystole, and ventricular tachycardia, and status epilepticus over 23 min. She was treated with supportive care and standard American Heart Association Advanced Cardiac Life Support (ACLS) recommendations for pulseless electrical activity and asystole. Fetal heart tones were not heard for 14 min during resuscitation, and remarkably both patients survived acute toxicity. The infant was born at 40 weeks' gestation without complication and showed no developmental delays at age 9 months.

Aggressive supportive care involves attention to airway, breathing, circulation, and neurologic disability. Maintenance of a patent airway, 100% oxygen administration, and if the patient is third trimester and is hypotensive, left lateral decubitus positioning along with two large-bore intravenous lines and aggressive fluid management are critical. Moving the patient to the left lateral decubitus position prevents the enlarged uterine fundus from compressing the inferior vena cava, which can decrease the central venous pressure 30–70%. If this position is not feasible, such as during chest compressions, manual leftward uterine displacement away from the inferior vena cava is also effective [24]. Cardiac drugs and unsynchronized cardioversion up to 300 J have not been found to be harmful to the fetus. The 2010 ACLS guidelines include an algorithm for pregnant cardiac arrest patients and specifically recommend using

typical ACLS drugs and doses [24, 25]. Open-chest cardiac massage has been suggested to reduce the required dose of epinephrine, which can cause vasoconstriction of the uteroplacental arteries [23, 26]. In contrast to most other instances of open-chest cardiac resuscitation, however, it is crucial not to cross-clamp the aorta because doing so would interrupt immediately uteroplacental blood flow.

If there is a change in mental status, dextrose, naloxone, and thiamine may diagnose and treat the related causes of central nervous system depression. The benefit of reversing a mother's respiratory depression and hypoxia from an opiate overdose far outweighs the risk of opiate withdrawal in the fetus. Fetal heart monitoring, which should be instituted during maternal stabilization, is an important factor if the fetus is of a gestational age at which it is potentially viable [27]. Emergent cesarean section may be necessary if there is fetal distress in the later stages of pregnancy. This therapy provides theoretical benefits to the mother by reducing circulatory load and to the fetus by removing it from a hypoxic/acidotic environment. A number of case reports have also described dramatic return of spontaneous circulation, after cardiac arrest in general, and recovery after perimortem cesarean section [24].

Decontamination

There is no approach to GI decontamination that could be applied empirically to all patients who overdose. Each patient must be assessed individually as to whether a particular method is indicated or contraindicated (see ► Chap. 3, "Therapeutic Approach to the Critically Poisoned Patient"). This approach applies to pregnant patients as well, with some additional considerations. As with most other pregnant poisoning topics, there has been no systematic evaluation of decontamination efficacy in pregnant patients.

Syrup of ipecac is contraindicated in pregnant patients because of increased abdominal and thoracic pressure with repeated emesis and may be

teratogenic [28, 29]. Currently, syrup of ipecac is essentially unavailable in the United States and should not be used in any poisoned patient (Grade III).

There are reports of gastric lavage in the pregnant patient. The indications and contraindications are the same as those for nonpregnant patients (see ► Chap. 3, "Therapeutic Approach to the Critically Poisoned Patient"). Because GI motility is slowed during pregnancy, delayed gastric lavage is theoretically attractive in the potentially life-threatening ingestion. However, the latest review of the literature related to nonpregnant patients, reenforced the principle that gastric lavage should not be routinely used in oral overdose, if at all [30] (Grade II-2-3). Gastric lavage is not a current, practical method of gastric decontamination and does not have a routine role in gastrointestinal decontamination of the pregnant patient, except in rare circumstances [31].

Activated charcoal can be an effective decontamination procedure, as it is in nonpregnant patients [32] (Grade II-2-3). AC itself is not absorbed and in theory should pose no direct harm to the fetus – in fact there have been no reports of fetal toxicity from AC. Similar to gastric lavage in pregnant patients, slowed gut motility may allow AC to be effective even if given more than 1–2 h after ingestion, in an awake, cooperative patient following a potentially lethal ingestion with no other effective antidote available. The activated charcoal dose for adolescents and older is 25–100 g [32]. Aspiration and bowel obstruction are the primary risks to the mother (Grade III). Although activated charcoal may decrease drug absorption if administered shortly after ingestion, there are no studies showing that its use alters the outcome of poisoned patients.

Cathartics, such as magnesium citrate and sorbitol, have no role in GI decontamination and should not be administered due to the potential for harmful outcome [33]. In most cases, one dose is safe, but with repetitive use, multiple doses can cause electrolyte abnormalities and possibly induce premature labor [28, 34]. Cathartics do

not add to the efficacy of AC. Many medical toxicologists prefer to administer AC as an aqueous suspension with no cathartics. This approach is not known to increase the likelihood of any charcoal-related adverse effects.

Whole-bowel irrigation (WBI) has been reported in pregnant patients [35, 36]. An iron overdose is one example in which this therapy may be used. In a report of an 18-year-old woman, 38 weeks pregnant, who ingested 55 tablets of prenatal iron, gastric lavage was attempted successfully, when the abdominal radiograph revealed tablets in the stomach. WBI with polyethylene glycol was started at 2 L/h and continued until the rectal effluent was clear. Deferoxamine therapy was also initiated. Fetal heart tones were in the range of 130–140 beats/min. The patient did well and had a normal delivery of a healthy infant in 5 weeks [35]. The indications and contraindications for WBI are the same for pregnant and nonpregnant patients [37] (see ► Chap. 3, “Therapeutic Approach to the Critically Poisoned Patient”).

Antidotes

There is minimal literature on the beneficial or harmful effects of antidotal therapy in pregnancy (Table 3). A small number of antidotes have had epidemiological studies for nonpoisoning indications [41]. Of these, atropine, calcium, and pyridoxine appear to be nonteratogenic. Ethanol and penicillamine are known teratogens, and both have alternative antidotes available. Methylene blue is a known teratogen in the setting of intra-amniotic injection for obstetric procedures, but its effects after intravenous administration in pregnancy are unknown. Based on the principle of improving maternal survival to improve fetal survival, giving a dose of methylene blue if indicated seems reasonable (Grade III) [41].

Aside from the above, only case reports or case series exist to provide insight on maternal-fetal effects or efficacy. These reports reveal little about the effect on the fetus but provide some observations about the effect on the mother. It is unlikely that a single exposure to antidotal therapy

would cause harm. There are well-documented cases of maternal and fetal mortality caused by withholding an antidote because of fear of inducing fetal teratogenicity [42, 43].

Enhanced Elimination

Although the supporting literature is limited, enhanced elimination with multiple-dose activated charcoal (MDAC) should be as effective and safe as single-dose AC in pregnant patients. As with single-dose AC, there is always the potential for aspiration. The few indications for possible MDAC therapy are the same as those in nonpregnant patients (e.g., ingestion of a potentially highly toxic amount of theophylline, phenobarbital, carbamazepine, dapsone, or quinine). MDAC for these drugs is supported in the literature because of effective “gut dialysis” or interruption of enterohepatic circulation in nonpregnant patients [44]. MDAC therapy is reviewed in detail in the ► Chap. 3, “Therapeutic Approach to the Critically Poisoned Patient”.

Hemodialysis in pregnancy is uncommon [45]. Most experience seems to be with patients with chronic renal failure or with acute renal failure from nontoxicologic causes [46–49]. In a study of 16 infants born to mothers on long-term hemodialysis with some residual renal function, it was found that none of the offspring had abnormalities, and all were delivered spontaneously at term [50].

The literature on extracorporeal therapies in pregnancy is limited to scant case reports. There is one case reported of use of hemodialysis in a pregnant patient at 11 weeks after a massive theophylline overdose [51]. In this case, hemodialysis was effective in increasing clearance of the drug and did not result in any appreciable complications for the mother. However, it is difficult to draw conclusions regarding fetal outcome as the mother elected to terminate her pregnancy 2 days after discharge. In another case report, a pregnant woman at 27 weeks gestation ingested paraquat in a suicide attempt [52]. After treatment with hemoperfusion, steroids, and cyclophosphamide pulse therapy, both she and the fetus survived, and

Table 3 Antidotes used in pregnancy [9]

Antidote	Historical pregnancy risk categories	Comments
Acetylcysteine [38]	B	Acetylcysteine can cross the human placenta
Ethyl alcohol	X	In chronic use, >2 g/kg/day in the first trimester two- to threefold higher risk for congenital malformations (about 10%)
	C	In acute therapy of toxic alcohol ingestion: use only if potential benefit outweighs the risks; ethanol crosses the placenta readily and enters fetal circulation
Amyl nitrite	X	
Antitoxin botulinum A, B, E	C	Use only if potential benefit outweighs the risks. It is unknown if the antitoxin antibodies cross the placenta
Antivenin (<i>Crotalidae</i>) polyvalent	C	Pregnancy is not a contraindication for antivenin therapy
Antivenin (<i>Micurus fulvius</i>) North American coral snake	C	Use only if potential benefit outweighs the risks. It is unknown if the antitoxin antibodies cross the placenta
Antivenin (<i>Crotalidae</i>) polyvalent (ovine) Fab	C	Pregnancy is not a contraindication for antivenin therapy
Atropine	C	Crosses the placenta; trace amounts appear in breast milk
Bromocriptine	C	Use only if potential benefit outweighs the risks
Calcium chloride	C	Crosses the placenta; appears in breast milk
Calcium gluconate	C	Crosses the placenta; appears in breast milk
Carboxypeptidase	C	
Charcoal	C	
Deferoxamine	C	Do not withhold chelation therapy for iron overdose solely due to pregnancy; has caused fetal abnormalities in animals
Digoxin immune Fab	C	No animal studies conducted
Dimercaprol	C	
Calcium EDTA	C	
Flumazenil	C	
Folic acid	A (C if dose exceeds RDA)	400 µg/day needed to prevent neural tube defects
Fomepizole	C	
Glucagon	B	
Hydroxycobalamin	C	
Insulin (R)	B	
Leucovorin	C	
Levocarnitine	B	
Lipid Emulsion [39, 40]	C	Recommended by Society for Obstetric Anesthesia and Perinatology for local anesthetic systemic toxicity at same doses as nonpregnant patients.
Methylene blue	C (D if injected intra-amniotically)	
Naloxone	B	
Octreotide	B	
Hyperbaric oxygen		Indicated for the treatment of pregnant patients when symptomatic or with a carboxyhemoglobin level >20%
Penicillamine	D	Correlated with cutis laxa in neonates
Physostigmine	C	

(continued)

Table 3 (continued)

Antidote	Historical pregnancy risk categories	Comments
Phytonadione	C (X if used in third trimester)	
Polyethylene glycol (high molecular weight)	C	
Pralidoxime	C	
Pyridoxine	A (C if dose exceeds RDA)	
Sodium bicarbonate	C	
Sodium nitrite	C	Has caused fetal death in humans and animals, avoid unless there is no other alternative (hydroxocobalamin)
Sodium thiosulfate	C	
Succimer	C	
Drugs of abuse	X	

EDTA ethylenediaminetetraacetic acid, *RDA* recommended daily allowance

delivered successfully with no apparent complications at 5-year follow-up.

Based on the above case reports and increasing usage in nonpoisoned patients, it seems reasonable to consider use of dialysis in the poisoned pregnant patient. If dialysis would be indicated in a nonpregnant patient, it is indicated in a pregnant patient as well (Grade III).

Specific Agents

Abortifacients

An abortifacient is any agent that a pregnant woman may use in an attempt to terminate her pregnancy. Many different substances have been used historically, including lead and quinine [53, 54]. Currently, in addition to over-the-counter medicines such as acetaminophen, aspirin, and iron with perceived abortifacient effects, herbal preparations are being used. Different cultures have their own contributions to the list of herbal abortifacients. Some representatives are cottonroot bark from Mexico; pulsatilla from India; and rue, apiol, cohosh, sage, and pennyroyal oil from the United States (Table 4) [56, 57]. In the United States, these herbal preparations are protected from scrutiny by the Dietary

Supplement Health and Education Act of 1994, which designates herbal products as food. This allows them to be regulated in a less stringent fashion by the FDA than pharmaceuticals.

In a prospective observational study of 43 women who ingested known or perceived abortifacients, ingestions were most common in the first trimester (79%). Acetaminophen was the most common drug ingested (30.2%), and polysubstances were common (35%) [58]. Five patients picked specific substances because they knew they were abortifacients. Minor toxicity generally was observed (81%) except in a tricyclic antidepressant overdose and a bupropion overdose. Fetal demise was not reported in a limited 3-day follow-up.

It has been questioned why women are using medical abortifacients when abortion is legal and accessible in many countries. The answer is thought to be the general movement away from traditional health care and toward herbal remedies [56]. Because of barriers to health care and increasing cost, a progressively greater proportion of the population is willing to try “self-help” remedies first. The dangers to women are the toxic effects of the agent on themselves, teratogenic effects if the fetus is carried to term, and complications from delaying a physician-assisted abortion when the abortifacient fails.

Table 4 Abortifacients

Agent	Class/active compound	Toxidrome	Toxicity	Comments
Angelica root – <i>Angelica archangelica</i>	Essential oil	Hypotension/shock	>1 mL ingested	Activated charcoal; supportive therapy
Black cohosh – <i>Cimicifuga racemosa</i>	Alkaloids including methylcytosine and acetin	Bradycardia, dizziness, nausea, vomiting, tremors, headache	Not documented	Activated charcoal; supportive therapy
Blue cohosh – <i>Caulophyllum thalictroides</i>	Alkaloid methyl cystine	Similar to nicotine: nausea, vomiting, muscle paralysis, seizures, tachycardia, hypotension	Not documented. Roasting eliminates toxicity	Activated charcoal; supportive therapy
Buckthorn bark – <i>Rhamnus cathartica</i> , <i>R. frangula</i> , <i>R. alnifolia</i>	Frangulin (anthroquinone)	Nausea, vomiting, abdominal cramping, diarrhea, potential renal toxin in large doses	1-g berries, mild toxicity in children; 20 berries or chewing of bark is necessary for severe symptoms	Activated charcoal; supportive therapy
Diethylcarbamazine	Antihelminthic-antifilarial agent that kills the parasite in the adult stage	Anorexia, dizziness, abdominal cramping, nausea, vomiting	>1 g	Activated charcoal; betamethasone can be used for hypersensitivity reactions; supportive care, multiple-dose charcoal may be useful for enhanced elimination
Ergotamine	Alkaloid; α -blocker; directly stimulates vasculature to vasoconstrict; serotonin antagonist	Tachycardia, hypertension, vasospasm, headache, seizure, hypotension, bradycardia, shock, peripheral vascular effects, nausea, vomiting, diarrhea	>1 mg/kg dose toxic; serum levels >1.8 ng/mL are toxic	Activated charcoal; warm extremities; vasodilators; intraarterial phenolamine for vasospasm, aspirin for antiplatelet effect; prostaglandins; heparin for hypercoagulable state; hyperbaric oxygen for limb ischemia; cyproheptadine to reverse vasoconstriction; supportive care
Mifepristone; approved in France as an abortifacient (1988)	Antiprogesterin agent acts on deciduous progesterone receptors, causing release of prostaglandin in the endometrium, resulting in uterine bleeding, contraction, and cervical dilation	Syncope, headache, nausea, vomiting, uterine pain, bleeding, rupture	A 600-mg dose can cause abortion of fetus within 56 days of amenorrhea	Activated charcoal; transfusion and curettage may be required for uterine bleeding; supportive care

(continued)

Table 4 (continued)

Agent	Class/active compound	Toxidrome	Toxicity	Comments
Mistletoe – <i>Phoradendron falvescens</i> , <i>P. macrophyllum rubrum</i> , <i>P. serotinum</i> , <i>P. tomentosum</i> ; <i>Viscum album</i>	Unknown	Nausea, vomiting, diarrhea, abdominal pain, bradycardia, ataxia, hypotension, seizures, cardiovascular collapse	>2–3 berries, teas, and extracts are toxic	Activated charcoal; supportive care
Poison hemlock – <i>Conium maculatum</i>	Similar to nicotine; stimulation of autonomic ganglion, then depression	Nausea, vomiting, ataxia, burning sensation in throat, tachycardia followed by bradycardia, seizures, paralysis of skeletal muscles and diaphragm, rhabdomyolysis, renal failure	Ingestion of any part of the plant	Activated charcoal; supportive care
Sodium chloride 20% by transabdominal intra-amniotic injection	Causes fluid shift from intracellular to extracellular space, causing destruction of cells	Disseminated intravascular coagulation, renal necrosis, uterine and cervical lesions, pulmonary embolism, pneumonia, hemorrhage	Labor starts in 12–24 h after injection	Supportive care
Misoprostol	Prostaglandin E ₁ analogue	Hypertension, tachycardia, abdominal cramps, rhabdomyolysis, fever, tremor	3 mg – moderate; 6 mg – death	Activated charcoal; supportive therapy
Pennyroyal – <i>Mentha pulegium</i> / <i>Hedeoma pulegioides</i>	Essential oil, pugelone; 22–98% active compound	Confusion, delirium, seizures, hepatic necrosis, renal failure, disseminated intravascular coagulation	5 mL toxic; 10–15 mL lethal; 50–100 g leaves = 1 mg oil	Activated charcoal; supportive therapy; <i>N</i> -acetylcysteine may decrease hepatic damage
Windflower – <i>Anemone pulsatilla</i>	Ranunculin, metabolized protoanemonin	Mucosal irritation/ ulceration, dizziness, paralysis, abdominal pain, diarrhea, vomiting, hypersalivation, renal injury	20 mg/kg can cause CNS and cardiac effects	Activated charcoal; supportive therapy
Quinine	Alkaloid from cinchona bark	Cardiovascular toxicity the same as quinidine, within 8–24 h; tinnitus, deafness, visual field constriction, blindness, vomiting, abdominal pain	>2 g	Multidose activated charcoal; sodium bicarbonate for QRS widening; lidocaine for arrhythmias; avoid class IA–IC antiarrhythmics

(continued)

Table 4 (continued)

Agent	Class/active compound	Toxidrome	Toxicity	Comments
Rue – <i>Ruta graveolens</i>	Pilocarpine, 1.4% quinoline alkaloids, furocoumarins, psoralens	Miosis, cholinergic crisis, headache, nausea, rash, hypotension	Not documented	Activated charcoal; supportive therapy
Savin/juniper – <i>Juniperus sabina</i>	Oil of sabinol and other volatile oils	Agitation; one large dose can cause catharsis, but repeated small doses can cause personality changes and renal damage	Not documented	Activated charcoal; supportive therapy
Mandrake – <i>Podophyllum peltatum</i>	Green fruit, foliage, roots contain podophyllum. Ripe fruit is nontoxic	Diarrhea, headache, respiratory stimulation, lethargy, coma in 12–24 h	Not documented	Activated charcoal; supportive therapy
Tansy – <i>Tanacetum/Chrysanthemum vulgare</i>	Thujone, tanacetin, boneol, camphor	Catharsis, personality changes, renal damage	Not documented	Activated charcoal; supportive therapy
Syrian Rue (<i>Peganum harmala</i>) [55]	Herbaceous plant, quinazoline alkaloids (vasicine and casicinone) are most likely abortifacients. Also contains MAO-A inhibitors	Confusion, CNS depression, hallucinations, diffuse tremors, nausea/vomiting, bradycardia	Not documented	Activated charcoal, supportive therapy

CNS: Central Nervous System, MAO: Monoamine Oxidase

All women who present with an overdose with the ability to become pregnant should have a pregnancy test (Grade III). If the pregnancy test is positive, the possibility of abortifacient usage should be addressed. Women who present with vaginal bleeding and pregnancy also should be questioned as to whether the vaginal bleeding was self-induced by an abortifacient.

Acetaminophen

Pregnant patients have wide accessibility to acetaminophen because it is considered “safe” in pregnancy when taken in therapeutic doses. Acetaminophen is contained in many other over-the-counter preparations. As a result, the chance of acetaminophen toxicity is increased in a polydrug overdose.

Human and animal studies have shown that acetaminophen crosses the placenta [59–61]. The fetus is protected from acetaminophen toxicity in the first trimester by the immature cytochrome P-450 system, which is unable to form the toxic metabolite *N*-acetyl-*p*-benzoquinoneimine. The fetus begins to have cytochrome P-450 activity at approximately 14 weeks of gestation [62]. The ability of 19-week and 22-week fetal liver tissue to form oxides verifies cytochrome P-450 activity at this age of development [63].

As with nonpregnant patients, *N*-acetylcysteine (NAC) is the prophylactic treatment for maternal acetaminophen overdose with possible hepatotoxicity. Pregnancy outcome is affected by time from ingestion until NAC administration. Spontaneous abortion was increased in pregnancies in which NAC was delayed in treating acetaminophen overdose [62]. One study in sheep showed that little NAC was able

to penetrate the placenta [64]. However, NAC later was shown to cross the placenta in rats. This discrepancy may be explained by the fact that sheep have a five-layer placenta and rats have a three-layered placenta similar to humans [38].

IV NAC has been detected in the umbilical cord blood both in poisoned and nonpoisoned patients. Fetal cord blood concentrations of NAC were measured in four newborns with mothers who overdosed on acetaminophen alone. The average NAC concentration was 9.4 $\mu\text{g/mL}$, within the therapeutic range in healthy volunteers [38, 65]. The use of intravenous NAC may be advantageous because oral NAC may induce emesis, and there is a greater maternal first-pass effect, which reduces the amount received by the fetus [64, 66]. However, there is no clinical evidence the route of NAC administration alters efficacy.

The outcomes of the mother and fetus are generally good after an acetaminophen overdose. Multiple case studies show that the outcomes of the fetus and mother are better in the first and second trimesters than in the third trimester [60, 67–73]. Even a massive 64-g ingestion at 15 weeks of gestation resulted in a good outcome [74], whereas in the third trimester fetal intratentorial hemorrhage, fetal demise, and maternal and fetal death have been documented [68–70]. Two large studies of women exposed to acetaminophen during all trimesters found no correlation between toxicity and malformations or miscarriages [75–77]. There appears to be no indication for a mother to terminate pregnancy if she overdosed on acetaminophen.

Although most acetaminophen ingestions result in recovery in the mother with a resultant normal delivery, heroic measures have been suggested in extreme cases of toxicity. Liver transplantation was attempted in one mother who developed fulminant hepatic failure after a repeat supratherapeutic overdose on acetaminophen at 19 weeks gestation [78]. Extensive measures were taken to tailor the patient's imaging and immune suppression to minimize risk to the fetus. The fetus appeared to do well immediately postoperative from the transplant. On postoperative day 14, the fetus began

developing rapidly progressive hydrocephalus and lateral herniation of the brain, leading to termination of the pregnancy.

Some authors advocate emergent delivery of the fetus in the third trimester if the mother has documented toxic levels of acetaminophen, but there is little to support this approach in the absence of hepatic failure [29]. Early vaginal or cesarean delivery may avoid potential complications if the mother becomes encephalopathic and coagulopathic. If there is fetal demise, emergent delivery also may be indicated if the fetus is retained and the mother has evidence of disseminated intravascular coagulation [68]. Exchange transfusion does not seem to be efficacious in the acetaminophen-poisoned neonate [60].

Treatment of pregnant patients for acetaminophen toxicity should be the same as that for nonpregnant patients, with some differences as noted previously (Grade III). See ► [Chap. 59, “Acetaminophen/Paracetamol”](#) for an in-depth discussion of acetaminophen toxicity.

Salicylates

Similar to acetaminophen, salicylates can be found in combination with other drugs in many preparations [79–81]. There is potential harm from salicylates taken therapeutically during pregnancy. Because of effects on neonatal coagulation and premature closure of the ductus arteriosus, salicylates are contraindicated in the third trimester of pregnancy [29]. Salicylates freely cross the placental membrane [82–85].

There are some variations from adult pharmacokinetics in the way the fetus reacts to the burden of a maternal salicylate overdose. Aspirin is hydrolyzed rapidly to salicylate. A small amount is excreted in the urine unchanged, whereas the remainder is metabolized to salicyluric acid, salicyl phenolic glucuronide, salicyl acyl glucuronide, and gentisic acid (Fig. 1). The largest fraction is converted to salicyluric acid, and the other pathways follow Michaelis-Menten kinetics. At low doses, salicylates are metabolized rapidly by first-order kinetics, whereas in higher doses,

Fig. 1 Disposition of the primary metabolite of aspirin, salicylic acid, at a single dose of 4 g (54 mg/kg body weight) in a healthy adult. The percentage values refer to

the dose. Oxidation produces a mixture of *ortho*- and *para*- (relative to original OH group) isomers

metabolism slows after a switch to zero-order kinetics. The mother and the fetus metabolize salicylate at a decreased rate after overdose.

The metabolism of salicylate was studied in the newborn of a mother who ingested 6.5 g of aspirin daily for the entire pregnancy [82]. The neonate metabolized a relatively larger fraction to salicyluric and gentisic acids, with little glucuronidation. As a result, salicylate elimination by the infant was much slower than that in the adult. Although it was noted that the elimination was delayed in large overdoses, when the amount of ingestion is decreased to 7 mg/kg, the elimination increased to adult rates.

The fetus is especially vulnerable to salicylate toxicity in the third trimester of development. In

an overdose, the measured serum fetal salicylate level is greater than the maternal concentration [86]. A greater proportion of salicylate enters the fetal brain than the maternal central nervous system. The fetus also has decreased capacity to buffer salicylate-induced metabolic acidosis. Lastly, metabolism and excretion of salicylate are decreased in the fetus, as discussed earlier [29, 87]. Therefore, logic dictates that treatment of the mother should be initiated at lower serum salicylate concentrations than one would initiate for a nonpregnant patient (Grade III). Urinary alkalization therapy might be warranted when serum salicylate levels increase to greater than approximately 25 mg/dL (180 μ mol/L) to account for these differences in fetal salicylate levels

(Grade III). Similarly, hemodialysis may be indicated at lower serum salicylate levels, since neonatal toxicity and intrauterine fetal demise have both been documented with maternal salicylate levels in the 50–60 mg/dL (360–439 $\mu\text{mol/L}$) range [88, 89].

Salicylate ingestion just before delivery can lead to maternal and fetal platelet dysfunction. After delivery, these neonates can have petechiae, purpura, cephalohematoma, GI bleeding, and intracranial bleeding [90, 91]. Other effects on the fetus from maternal salicylate use are hyperbilirubinemia resulting from displacement from albumin, lower birth weight, and increased mortality [92]. Increased risk of congenital abnormalities and hypoglycemia are uncommon. It is believed that the antiprostaglandin effects of salicylates can cause complications in the mother as well [93]. The maternal effects of chronic salicylate ingestion include longer gestational periods, prolonged labor, increased risk of hemorrhage, and higher rates of cesarean [86].

Treatment of pregnant patients with salicylate toxicity should be the same as that for nonpregnant patients, with the caveat discussed previously (Grade III). In acute toxicity, GI decontamination should begin with AC, which is effective in binding salicylate. The total amount remains debatable, but at least a 1 g/kg dose up to a ratio of 10 g of activated charcoal: 1 g of salicylate, is recommended. Multiple determinations of serum concentrations of salicylate are needed to monitor for continued absorption and hence dictating the need for further activated charcoal. ► [Chapter 63, “Salicylates”](#) provides an in-depth discussion of the treatment of salicylate toxicity.

Because of the high toxicity of salicylate to the fetus, fetal monitoring may be needed to assist in the determination of the need for emergent delivery in a fetus of potentially viable gestational age. Emergent delivery is considered optimal treatment by some [29]. If the time of maternal overdose approximates the expected delivery date, the neonatologist should be alerted about the increased risk of platelet dysfunction.

Iron

Although accidental iron overdose has decreased substantially in the pediatric population because of changes in iron supplementation packaging, intentional overdose in the adult remains a serious ingestion. Iron is readily available to the pregnant woman because it is prescribed routinely during the prenatal period. As a result, it is a concern for potential overdose in pregnancy.

Iron toxicity injures the human body through multiple mechanisms: peroxidation of biologic membranes, inhibition of oxidative phosphorylation, and formation of free hydrogen ions as a by-product of the change from the ferrous to the ferric state, causing metabolic acidosis [94, 95]. Iron seems to have little direct toxicity to the fetus. It does not diffuse passively across biologic membranes but acts through a receptor-mediated endocytosis. A study of iron toxicity in pregnant sheep showed that elevated maternal serum iron concentrations are not reciprocated in the fetal circulation [21]. Human case reports also support this finding [42, 96]. Iron does not affect the fetus directly but does so indirectly through poisoning of the mother. The placenta provides an effective barrier to iron, leaving the fetus reliant on the well-being of the mother for its survival [97].

Two other components of general iron toxicity are present in pregnant patients. The peak serum iron concentration occurs in the range of 2–4 h, and using the total iron-binding capacity to predict the severity of poisoning is inaccurate [98]. Treatment must focus on the sum of many different data points to determine what is most appropriate. Greater than 60 mg/kg ingestion, hypotension, mental status depression, metabolic acidosis, GI bleeding, shock, and serum iron level greater than 500 $\mu\text{g/dL}$ (89 mmol/L) all are signs of a severe iron poisoning and are indications for deferoxamine administration (Grade III evidence).

GI decontamination after iron poisoning is controversial. Some authors support gastric lavage if a pregnant patient presents less than 1 h after ingesting a potentially toxic dose, but the proper equipment and training of staff has made

this technique largely unavailable, and should likely be avoided in most circumstances. Alternatively, WBI can be administered safely in the pregnant patient if significant quantities of iron-containing radiopacities are visualized on abdominal radiographs after recent ingestion. Activated charcoal may be used if a coingestant is suspected, but it does not adsorb iron itself. Ultrasound is the imaging modality of choice in pregnant patients because it causes no ionizing radiation, though its ability to identify pills in the setting of overdose remains in question [99, 100]. Pregnancy should not be a contraindication to a flat plate of the abdomen in the case of an iron overdose, overdose because of the very low dose of radiation and the benefits outweighing the risks. A kidney, ureter, and bladder film potentially could avoid toxicity for the mother and fetus by alerting the clinician to the diagnosis of iron toxicity while guiding decontamination therapy with WBI. Adverse side effects from the amount of radiation are trivial compared with the potential threat of fetal toxicity after a substantial iron ingestion.

Deferoxamine is the antidote for iron poisoning. It chelates free iron and is excreted by the kidneys. The indications were listed previously, but some clinicians take a more conservative approach and treat a pregnant patient with a serum iron concentration greater than 350 $\mu\text{g/dL}$ (62.5 mmol/L) [97]. The usual intravenous dose of 15 mg/kg/h with the upper limit of 6 g in 24 h is often quoted and still cited in the package insert [101]. The reason for this limit is to avoid hypotension and acute lung injury. A firm standard for the limits of deferoxamine therapy has yet to be shown in clinical trials.

Previously, deferoxamine was considered dangerous to give to the pregnant patient because of fears of teratogenicity. There have been reports of skeletal abnormalities in animals exposed to high doses of deferoxamine [96, 101]. In contrast, reviews of multiple case studies have shown no direct link between deferoxamine treatment in humans with iron toxicity and teratogenicity [102–105]. More reassurance of the safety of deferoxamine in pregnancy is provided by the fact that deferoxamine does not cross the placenta

in the ovine model [21]. The clinical pharmacology of deferoxamine is discussed in detail in ► Chap. 143, “Deferoxamine”.

It follows that if iron itself has difficulty passing the placenta and if deferoxamine does not penetrate the placenta well, neither iron nor deferoxamine directly contributes to fetal injury. In this overdose, the mother has more potential morbidity than the fetus. The primary concern is the mother’s clinical state. This constitutes a classic example of the dictum that the future of the mother and the fetus relies on optimal treatment of the mother. Iron toxicity is discussed in detail in the ► Chap. 67, “Iron”.

Carbon Monoxide

Carbon monoxide is an endogenous by-product of heme degradation in humans (75% hemoglobin + 25% other blood pigments) [106]. While no longer the leading cause of poisoning death in the United States, CO was still responsible for 14,289 calls to poison centers in 2013, with 60 of these cases being fatalities [1]. The clinical signs and symptoms of CO poisoning mimic the presentations of many illnesses, such as viral syndrome or gastroenteritis. The best way to diagnose CO poisoning is to consider it often in differential diagnoses. It cannot be overstated that one needs a high degree of suspicion to discover CO poisoning.

During a normal pregnancy, endogenous production of CO increases carboxyhemoglobin (COHb) 20–40% above normal levels [106, 107]. Of this increase in maternal COHb, 30–40% is from an increase in maternal erythrocyte load. The fetus contributes 15% of the COHb increase. The instigator of this increase is progesterone, which induces the catabolism of hemoglobin by hepatic microsomal enzymes. The minute ventilation also increases during pregnancy. The baseline increased burden of CO and the increased minute ventilation make the pregnant woman more susceptible to CO poisoning.

The pathogenesis of CO toxicity is twofold: CO generates oxidative stress, and it binds to

heme-containing proteins, such as hemoglobin, myoglobin, and cytochrome *aa3* [106]. CO has an affinity for hemoglobin 250, 25, and 1 time greater than oxygen for hemoglobin, myoglobin, and cytochrome *aa3*, respectively. This binding leads to systemic hypoxia and a shift of the oxygen-hemoglobin saturation curve to the left, with a transformation of the curve to a hyperbolic shape [107]. There may be direct toxicity to cardiac tissue as a result of the replacement of oxygen with CO in cardiac myocytes. Uncoupling of oxidative phosphorylation causes an increase in free hydrogen ions, leading to metabolic acidosis. Fetal hemoglobin complicates the situation because its oxygen binding curve is already hyperbola shaped and steep at low pressures of oxygen. Decreased ability of tissues to extract oxygen from the fetal hemoglobin and increased susceptibility to a precipitous drop in oxygen saturation result.

In acute maternal CO exposure, the CO slowly crosses the placenta by passive diffusion [108]. In humans, the fetal COHb concentration reaches maternal levels in 14–24 h and a state of equilibrium in 36–48 h, with percent fetal COHb 15–20% greater than the maternal percentage [106, 107, 109]. In acute exposure, death by anoxia occurs well before COHb concentrations increase [110]. In chronic CO exposure, the CO level in the fetus progressively increases, and the critical level is 60% [109]. The CO elimination half-life is 2 h in the mother and 7 h in the fetus.

The sum of the effects from fetal hemoglobin, prolonged elimination, delayed peak in fetal COHb concentration, and elevated concentration of COHb in the fetus places the fetus at greater risk for morbidity and mortality than the mother. There are multiple case reports of the mother's exhibiting minimal to no toxicity, with simultaneous significant adverse effects or death in the fetus [109–112]. Similar to the situation in nonpregnant patients, the CO level, expressed as percent COHb, does not correlate well with severity of toxicity. Fetal COHb levels are not realistically obtainable, making a history of exposure along with clinical signs and symptoms in the

mother the only guide for therapy. Multiple sources point out that maternal symptoms of altered mental status, neurologic deficits, seizures, and coma are better predictors of fetal toxicity than are COHb concentrations [108, 109, 113].

Teratogenicity varies with the timing of the exposure. Case reports suggest the possibility that exposure in the embryonic stage leads to neurologic, skeletal, and cleft palate deformities. During the fetal phase, anoxic encephalopathy and growth restriction may result. In the third trimester, prematurity delivery is reported and possibly decreased immunity, right-sided cardiomegaly, and delay in myelin formation [106, 114].

Primary treatment of CO toxicity involves removal of the mother from the source of exposure and starting therapy with 15 L of 100% oxygen via nonrebreather mask. HBO therapy has been advocated as the treatment of choice for pregnant patients exposed to CO [106, 115]. HBO therapy can reduce the elimination half-life of CO from 4 to 6 h on room air, to roughly 20 min. Normobaric oxygen and HBO therapy increases dissolved oxygen, accelerates dissociation of CO from hemoglobin, and shifts the oxygen-hemoglobin curve back to the right.

Nonetheless, the efficacy of HBO therapy in preventing neuropsychiatric sequelae from CO in the pregnant patient, which is the endpoint of the major studies, is unknown. As expected, pregnant patients have been excluded from HBO research as a therapy for CO poisoning. A Cochrane Review in 2011 found conflicting evidence in existing randomized controlled trials regarding HBO therapy for CO poisoning in nonpregnant patients [116]. Therefore, there are no evidence-based recommendations for HBO therapy for pregnant patients poisoned from CO, only opinions (Grade III).

Suggested indications for HBO therapy in the pregnant patient are a maternal COHb level greater than 15–20%, maternal neurologic signs or symptoms, and evidence of fetal compromise [117]. If maternal or fetal signs of CO toxicity persist 12 h after initial HBO therapy, a repeat session has been proposed [106, 118]. It has been recommended that 100% oxygen continue

five times longer in pregnant patients than standard treatment duration in nonpregnant patients to allow greater removal of CO from the fetal hemoglobin (Grade III) [108, 109, 113].

In addition, there are specific areas of concern for the fetus treated with HBO. High PO₂ is known to be teratogenic and to cause retinopathy, cardiovascular defects, and premature closure of the ductus arteriosus [118]. An animal study showed similar adverse effects [18].

Several human case reports and studies strongly advocate HBO therapy in pregnant patients [18, 108, 109, 113, 119, 120]. The safety of HBO therapy in pregnant patients was studied prospectively in 44 women, all of whom tolerated the procedure well, and no morbidity was seen in the mother or the fetus [121]. A prospective French series from 1983 to 2008 found no difference in early childhood development (as late as age 6 years) between those who received HBO for CO in utero and unexposed age matched controls, further emphasizing the apparent safety of HBO in pregnant patients [122].

In addition to the described standard therapy of CO poisoning, fetal heart monitoring is indicated in the late second and third trimesters. Poor variability and late decelerations are indications of fetal distress. One review article cautioned that immediate delivery of the fetus before HBO therapy carries a high risk of perinatal death. The authors concluded that HBO therapy should be considered before performing an emergency cesarean section [106]. This recommendation is based solely on theoretical considerations, however, and there are no data to support this from clinical trials.

Cyanide

Cyanide is a cellular asphyxiant that binds to and inhibits cytochrome oxidase at cytochrome a₃ in the mitochondria electron transport chain. It prevents the conversion of electron energy into the creation of ATP, leading to seizures, dysrhythmias and hypotension, metabolic acidosis and hyperlactatemia from anaerobic metabolism. The most probable exposure of the pregnant patient to

cyanide is in the gaseous form found in smoke inhalation, but ingestion of a cyanide salt, organic compound or nitroprusside infusion are possible as well.

Pregnant women exposed to cyanide from smoke inhalation or other sources are not well studied, leaving no guidance about this unique population. Roderique et al. report a case of a 32-year-old woman, G2P1, 36 weeks gestation, who was intubated and treated with 5 g of IV hydroxycobalamin after closed space smoke inhalation [123]. She was extubated after clinical improvement and delivered a healthy infant. The amniotic fluid and urine was noted to have the characteristic red color seen after hydroxycobalamin infusion, indicating placental transfer and fetal elimination of hydroxycobalamin. There was no long-term follow-up.

Nitroprusside contains cyanide molecules that are released as the drug is metabolized. This can cause cyanide toxicity if the infusion exceeds 2 mcg/kg/min or continued for a prolonged time period. Because nitroprusside crosses the ewe placenta, this animal model was used to determine if prophylactic sodium thiosulfate could prevent cyanide toxicity in the pregnant ewe. There was successful reduction in uptake of cyanide in RBCs in the mother and the fetus, despite a follow-up study revealing sodium thiosulfate does not cross the ewe placenta [124, 125].

Hydroxycobalamin, sodium nitrite, and sodium thiosulfate are antidotes available for the treatment of cyanide toxicity in the pregnant patient (Grade III) and are considered category C in pregnancy. Amyl nitrite is not recommended especially with more efficacious and safer pharmaceuticals like hydroxycobalamin and sodium thiosulfate. See the ► Chap. 97, “Cyanide: Hydrogen Cyanide, Inorganic Cyanide Salts, and Nitriles” chapter for further information on cyanide toxicity.

Cocaine

Cocaine is a common drug of abuse in women of childbearing age [126]. One study found that 17% of urban women enrolled in prenatal care admitted

to using cocaine once during their pregnancy [127]. Smoking crack cocaine is the most common route of exposure, and most pregnant women who use this substance do not receive any prenatal care [128, 129]. Some women do not realize they are pregnant, whereas others surmise the pregnancy is lost and decide to continue using cocaine [130]. Still others falsely think that cocaine speeds labor. Cocaine can increase the length of labor, however, and exacerbates pain sensation [131].

The manifestations of cocaine toxicity are the same as those in any nonpregnant patient. Hyperthermia, hypertension, tachycardia, agitation, seizures, stroke, myocardial infarction, intracerebral hemorrhage, and aortic dissection are possible results of cocaine use. The unique complications associated with cocaine use in pregnancy are abruptio placentae, decreased fetal growth, preterm labor, urinary congenital abnormalities, neurobehavioral abnormalities, and fetal demise [132–134].

The pregnant patient theoretically is at enhanced susceptibility to cocaine poisoning due to reduced cholinesterase levels [135], causing her to have decreased ability to metabolize cocaine. The fetus also has reduced levels of cholinesterase, but the placenta has sufficient activity to allow metabolism of some of the cocaine before it crosses the placenta and affects the fetus [136]. Cocaine administered to the pregnant ewe caused increased vascular resistance, decreased uterine flow, increased fetal heart rate and blood pressure, and lower fetal oxygen content [137]. Progesterone may increase cocaine's cardiovascular toxicity in the pregnant patient [138].

Benzodiazepines are the medication of choice to treat the agitated, seizing, or tachycardic patient who is manifesting signs of cocaine toxicity. Diazepam and lorazepam are often considered contraindicated in pregnancy out of concern for teratogenic risks. Despite this warning, in the case of a pregnant woman with cocaine toxicity who presents with seizures, agitation, and hyperthermia, benzodiazepines are effective at diffusing cocaine toxicity and may decrease morbidity and mortality [139]. The teratogenic risk of benzodiazepines is likely minimal except for a small association with oral clefts [140]. Further, mothers

who attempt suicide by single large benzodiazepine overdose show no increase in congenital abnormalities [141]. There may be respiratory depression on delivery of a fetus from a mother recently treated with benzodiazepines, but the benefits outweigh the risks. If efforts to halt seizures are refractory to benzodiazepines, phenobarbital is preferred over phenytoin owing to the latter's known teratogenic effects on the fetus (Grade III). Antihypertensives, such as nitroglycerin, may be used for hypertension, and rapid external cooling for hyperthermia is essential. If chest pain is present, investigation and treatment of possible myocardial ischemia are warranted. Cocaine toxicity is discussed in greater detail in ► Chap. 75, "Cocaine."

Opioids

The epidemic of opioid abuse has been well recorded and described previously [142]. This epidemic is also seen among pregnant patients, where 0.1% of pregnant women report having used heroin, 1% report nonmedical use of opioid pain medications, and 2.6% of pregnant women in one urban teaching hospital tested positive for opioids [143]. Some opioids, particularly codeine, have been associated with birth defects including congenital heart defects [143]. Chronic heroin risk has been associated with a variety of poor fetal outcomes including fetal growth restriction, preterm labor, and fetal death. In the case of heroin, there is a theory that these effects are from both repeated exposure and repeated withdrawal.

The treatment of opioid withdrawal creates a concern regarding naloxone use in pregnancy. While opioid withdrawal is typically not life threatening, it can precipitate preterm labor and fetal distress, so we recommend that naloxone be used only in the case of maternal overdose with hypoxia and potential airway compromise in order to save the mother's life (Grade III) [143]. Similarly, pregnant patients who may be dependent on opioids should be observed for signs and symptoms of withdrawal and managed as needed to prevent fetal distress (Grade III).

Other Intoxications

There have been many reports of other poisonings and toxic syndromes in pregnancy. Some of these cases are summarized in Table 5. All recommendations are Grade III.

Toxicity of Pregnancy-Related Medications

Magnesium Sulfate

The magnesium cation is involved in many physiologic reactions and regulation of ion channels. Most is stored in bone, leaving only 1% free in the serum. Magnesium sulfate is used as an anticonvulsant in pregnant patients with eclampsia or severe preeclampsia. In most cases, magnesium sulfate has been shown to be safe and effective [159–161].

The true mechanism of magnesium's action is not documented clearly. It affects many different systems, which may contribute to the antiepileptic properties of this medication. Magnesium is a calcium antagonist and causes systemic and cerebral vasodilation. It increases cyclic guanosine monophosphate levels, which may act as a vasodilator by increasing nitric oxide levels and decreasing endothelin-1. Magnesium can slow conduction through the myocardium and decrease inotropy in high doses. It also can protect neuronal tissues from injury by blocking calcium channels directly in *N*-methyl-D-aspartate receptors. Finally, magnesium can decrease acetylcholine release from the presynaptic neuron onto the motor endplate, by blocking influx of presynaptic calcium. The major importance of this effect is loss of diaphragm function [159, 161, 162].

The toxicity of magnesium probably depends more on its rate of administration than the duration or the total dose, except in extreme circumstances. When magnesium administration exceeds its rate of renal clearance, its serum concentrations increase and may result in toxicity. There are many different regimens used in pregnancy, including regimens involving the intravenous and intramuscular routes with different

target serum magnesium concentrations. At levels of 3.8–5 mmol/L, the patient may have flushing, headaches, blurred vision, nausea, nystagmus, lethargy, hypothermia, urinary retention, loss of the patellar reflex, or ileus. Respiratory muscle paralysis may occur at concentrations of 5–6.5 mmol/L. Cardiac conduction disturbances occur at magnesium serum concentrations of 7.5 mmol/L, and cardiac arrest may ensue at levels of approximately 12.5 mmol/L [162].

Magnesium toxicity affects the mother and the fetus. For the mother, this toxicity typically occurs by an error in the rate of administration [163]. In a case report of a 23-year-old woman at 32 weeks' gestation, the patient had a cardiopulmonary arrest after 25 g had been administered instead of 1 g/min for a total dose of 4 g [164]. The mother also is in danger when magnesium therapy is combined with polarizing and nondepolarizing agents because of prolonged respiratory paralysis [162]. Hypotension can be a complication when magnesium is used with epidural blocks. Because of their calcium channel-blocking properties, magnesium combined with nifedipine can lead to profound hypotension [162].

The effect of magnesium on the fetus is variable. The classic result in the neonate is hypotonicity, which may affect diaphragmatic function. In a retrospective cohort analysis of more than 6600 women with preeclampsia treated with magnesium, 6% of the infants were diagnosed with hypotonia [165]. Magnesium toxicity in the mother also increases the rate of perinatal mortality, even when there is little effect on the mother [166]. Magnesium therapy may be detrimental to the fetus in the scenario of maternal hemorrhage. A study of pregnant ewes at 123 days' gestation found increased mortality in the fetuses whose mothers were treated with magnesium therapy during maternal hemorrhage compared with saline therapy. The magnesium may have inhibited the natural response to hypoxemia in the fetus [167]. Another study in pregnant sheep found that magnesium did not impair cardiac output, however, or increase fetal death during maternal hemorrhage [168].

The treatment of magnesium toxicity involves attention to airway, breathing, and cardiovascular

Table 5 Poisonings in pregnant patients

Toxin	Clinical course/treatment	Outcome	Recommendations
Methanol [144]			
Editorial: 1. Freely crosses the placenta 2. Alcohol dehydrogenase activity 10% in wk 10–16	See ► Chap. 88, “Methanol and Formaldehyde”	?	1. Caution alcohol known teratogen 2. Blockade of alcohol dehydrogenase with ethanol and hemodialysis 3. Published before fomepizole 4. Emergent delivery if fetal distress
Ergotamine [145]			
Case report: 17-year-old G ₁ P ₀ , 35 weeks gestation, ingested 20 mg of ergotamine 3 h PTA and presented confused with normal vital signs	1. Gastric lavage 2. FHT 170 beats/min; NST 2 h after arrival was reactive but unsatisfactory 3. Uterine contractions once/min	1. 8 h later, fetal death and mother had myocardial ischemia 2. Fetal death presumed from uterine contractions and arterial spasm	1. Fetal death presumed from uterine contractions and arterial spasm 2. Early delivery because of deleterious fetal effects without morbidity to mother
Neuroleptic malignant syndrome [146]			
Case report: Multitpara 25 {6/7} weeks was in ICU for respiratory failure and pneumonia. She was treated with increasing doses of haloperidol for agitation	1. Haloperidol discontinued 2. Bromocriptine 2.5 mg tid 3. Dantrolene 40 mg pid 4. The above medications were discontinued in 12 days 5. Biweekly NST and weekly amniotic fluid tests	1. 4 weeks after admission the patient was discharged 2. Healthy female infant born at 38 {4/7} wk	1. Correct fluid, electrolytes, and fever 2. Bromocriptine is safe to use in pregnancy 3. Limited experience with dantrolene in the literature, but no neonatal effects noted in this case
Carbamazepine [147]			
Case report: Term breast-fed boy born to a mother on carbamazepine for epilepsy with asphyxia at birth and hepatic dysfunction in the first week of life. After recovery, at the fifth week of life, cholestatic hepatitis	1. Ruled out nontoxic etiologies 2. Liver biopsy showed bile duct lymphocytic infiltrates, hepatocellular cholestasis, and microvesicular fatty changes 3. Maternal carbamazepine level 12.4 mg/L 4. Fetal carbamazepine level 0.5 mg/L	No specific details of outcome	Consider drug-induced cholestatic hepatitis in a mother on carbamazepine during pregnancy and nursing
Snake envenomation			
Prospective observational study in Sri Lanka [148] 1. 39 pregnant women 62% snakes identified	26% received antivenom	1. 55.5% had adverse reactions (one patient required epinephrine) 2. No maternal deaths 3. 29% abortions and one malformation (all abortions occurred <18 weeks gestation)	1. Snake bite in first trimester with systemic envenomation results in a poor outcome (second trimester is better, and third trimester is the best outcome) 2. Did not find snake antivenom to be a risk factor for fetal death

(continued)

Table 5 (continued)

Toxin	Clinical course/treatment	Outcome	Recommendations
Case series of three patients envenomated by <i>Trimeresurus stejnegeri</i> (Habu) while pregnant [149]	2/3 received equine-derived Fab2 antivenom	All mothers and children alive and well 6–10 years post envenomation and treatment without apparent abnormality	Antivenom administration did not appear to significantly worsen fetal outcome
<i>Amanita phalloides</i> [150]			
Case report: 22-year-old, 11 week gestation, ate mushrooms and 10 h later gastrointestinal symptoms 36 h AST/ALT = 663/607 U/L Peak AST/ALT = 4127/2903 U/L Factors V, II, VII, X decreased by 20%, 24%, 23%, 13%, respectively	1. Silybinin 20 mg/kg q 6 h 2. Activated charcoal 3. NAC IV per protocol 4. Abdominal ultrasound 5. Fetal movements and cardiac activity monitored	1. Day 9 discharged 2. 38 weeks delivered healthy infant 3. 2-year follow-up both patients doing well	1. During first trimester, invasive prenatal tests must be avoided 2. The therapy mentioned may be of benefit 3. Abortion is not recommended 4. Pregnancy is not a contraindication for transplant
Phenytoin [151]			
Case report: 18-year-old, eighth month of pregnancy, took 22 g of phenytoin and 2.4 g of phenobarbital Presented alert with stable vital signs	1. Intubation 2. Gastric lavage 3. Hemodialysis 138 h postingestion	Mother and infant did well	1. Hemodialysis did not seem to change clinical scenario 2. Questionable how much phenytoin or phenobarbital crosses the placenta
Vaginally administered cocaine [152]			
Case report: 21-year-old G ₂ P ₁₀₀₁ , 16 weeks gestation, presented unresponsive after boyfriend inserted 1.5 g of cocaine into vagina	1. 0 pulse, 0 BP: intubation, CPR, dopamine 2. Seizure: phenobarbital 3. Cocaine and benzylecgonine positive in urine and vaginal wash 4. Head CT: edema 5. Neonate delivered at 33 weeks by cesarean section: betamethasone given, Apgar 1 and 4 at 1 and 5 min, respectively, hydrocephaly and no brainstem on brain CT	1. Mother died 8 months after admission 2. Fetus died on 10th day of life	1. Treatment of acidosis and seizures is a priority 2. Fatal dose in 70-kg person is 1.4 g intranasally, 750–800 mg SC, IV, or inhaled
Misoprostol – PO [153]			
Case report: 19-year-old G ₃ P ₁₀₁₁ , 31 week gestation, ingested 30 tablets of misoprostol, 200 µg, and 4 tablets of trifluoperazine, 2 mg, 2 h PTA	1. Gastric lavage and activated charcoal 2. 1 h PTA no fetal movement by ultrasound 3. Uterine tetany, acidosis, hyperthermia, tachycardia, hypertension, hypoxemia treated with supportive care 4. Dead fetus delivered 2 h postpresentation 5. CPK peaked at 5849 U/L 25 h postingestion	1. Fetal death, autopsy remarkable for diffuse head and upper-body bruising 2. Maternal survival	1. Rapid onset of symptoms and resolution <12 h consistent with misoprostol pharmacokinetics 2. 400 µg of misoprostol q 4 h is the most administered to induce labor; ingestion of 6000 µg most likely led to fetal death. Uterine contractions and placental dysfunction probably led to death, but direct toxicity cannot be ruled out

(continued)

Table 5 (continued)

Toxin	Clinical course/treatment	Outcome	Recommendations
Misoprostol – vaginal [154]			
Case report: 25-year-old G ₃ P ₀₀₂₀ , 36 weeks gestation, intravaginally administered 6000 µg of misoprostol and ingested 600 µg, 3 h PTA	<ol style="list-style-type: none"> 1. Rapid chills, cramping, emesis, confusion, uterine contractions 2. 3.5 h postingestion temperature 106 °F, systolic BP 80 mmHg 3. Ultrasound 3.5 h postingestion, no fetal movement 4. Nonviable fetus delivered by cesarean section 5. Treatment of mother was supportive, including intubation with a paralytic to control agitation and hyperthermia 	<ol style="list-style-type: none"> 1. Fetal death, with normal anatomy and partial placental abruption 2. Maternal recovery in 16 h 	<ol style="list-style-type: none"> 1. Activated charcoal if oral ingestion 2. Vaginal lavage with saline 3. Supportive care with benzodiazepines, fluids, cooling, paralysis
Diazinon [155]			
Case report: 42-year-old G4P0 at 26 weeks was unintentionally exposed to diazinon while cleaning a small unaired bathroom	Treated with atropine and pralidoxime, recovered within 7 days	Healthy child delivered at term 12 weeks later	Treat organophosphate exposures in pregnant patients similarly to nonpregnant patients
Diphenhydramine [156]			
Case report: 19-year-old gravida 1, 26 weeks gestation, ingested 35 25-mg diphenhydramine tablets, and acetaminophen	<ol style="list-style-type: none"> 1. Hypertension, tachycardia treated supportively 2. 6-mg bolus followed by 3 mg/h IV magnesium sulfate halted the uterine contractions 	<ol style="list-style-type: none"> 1. No comment on future delivery of the fetus, but no morbidity or mortality during monitoring in this case 2. Maternal recovery 	<ol style="list-style-type: none"> 1. Supportive care 2. IV tocolysis
Chemotherapy [157]			
84 children who were exposed in utero to various chemotherapy regimens for maternal hematological malignancies, many during the 1st trimester	No significant change was made to any of the treatment regimens to account for maternal pregnancy	All children were born without apparent abnormality with follow-up of 6–29 years. 12 second generation children were also without abnormality	Full dose chemotherapy for aggressive hematological malignancies is reasonable, including in the first trimester
Paraquat [52]			
Case report: 27-year-old G5P4A1 at 27 weeks drank 40 mL of 24% paraquat in a suicide attempt and presented within 2 h	Received activated charcoal, magnesium citrate, hemoperfusion x2, cyclophosphamide pulse therapy, steroids	Mother and fetus survived. Child born at term, no abnormalities noted by age 5 years	Cyclophosphamide, steroids, and hemoperfusion should be considered in third trimester

(continued)

Table 5 (continued)

Toxin	Clinical course/treatment	Outcome	Recommendations
Brodifacoum [158]			
Case report: 19-year-old, 22 weeks gestation, ingested a box of brodifacoum 8 days prior	<ol style="list-style-type: none"> 1. Brodifacoum level of 220 ng/mL 2. PT >60 s, INR >20 3. Transfusion of 2 U PRBCs, total of 70 mg phytonadione IV and 625 mg orally 4. FHT 150 beats/min 	<ol style="list-style-type: none"> 1. Discharged on hospital day 12 (21 days postingestion) 2. Fetus delivered term, no fetal hemorrhage, no abruption, no problems at 1-year follow-up 	<ol style="list-style-type: none"> 1. No fetal hemorrhagic or teratogenic effects noted 2. Treatment supportive

AST/ALT aspartate aminotransferase/alanine aminotransferase, *BP* blood pressure, *CPK* creatine phosphokinase, *CPR* cardiopulmonary resuscitation, *CT* computed tomography, *FHT* fetal heart tones, *ICU* intensive care unit, *INR* international normalized ratio, *IV* intravenous, *NAC* N-acetylcysteine, *NST* nonstress test, *PRBCs* packed red blood cells, *PT* prothrombin time, *PTA* prior to arrival, *SC* subcutaneous(ly)

status. Intubation and vasopressors with aggressive supportive care are the mainstays of treatment. Intravenous calcium may serve as an antidote to the effects of magnesium toxicity. Maintaining a urine output of at least 100 mL/4 h also can ensure elimination of the magnesium [162] (Grade III evidence). Maternal hemodialysis may be indicated in cases of severe hypermagnesemia.

Methotrexate

Methotrexate (MTX) is used to abort ectopic pregnancies and to treat gestational trophoblastic disease. MTX destroys actively dividing cells because it acts as an analogue of folate (Fig. 2). MTX replaces folate at its binding site on dihydrofolate reductase and thymidylate synthetase (Fig. 3). The end result is inhibition of DNA synthesis, leading to cell death. MTX exhibits profound dose-dependent toxicity. It may cause nausea, vomiting, mucositis, pleuritis, pericarditis, peritonitis, liver injury, renal failure, anemia, and leucopenia at therapeutic doses [169–171].

MTX overdose has followed intravenous, oral, and intrathecal routes. Multiple doses of AC may be effective in lowering the serum MTX concentrations [172]. Urinary alkalinization may ion-trap MTX in the renal tubules and enhance its elimination (Grade II-3 recommendation). Leucovorin is the antidote of choice for MTX overdose (Grade II-3 recommendation). Its dosage depends on the

serum MTX concentration. The standard dose is 10 mg/m² intravenously or orally every 6 h. This antidote should not be delayed while waiting for an MTX level. Intrathecal MTX overdoses may be treated by cerebrospinal fluid drainage, exchange, or transfusion [173]. Carboxypeptidase is a antidote that directly deactivates MTX. In a severe overdose, granulocyte-macrophage colony-stimulating factor has been used to treat pancytopenia with apparent success [174]. MTX toxicity is described in detail in ► Chap. 60, “Methotrexate.”

Vagotonics/Tocolytics

Vagotonics are medications used to increase contractions of the uterus. Methylergonovine in overdose can cause hypertension, chest pain, myocardial infarction, headache, vertigo, nausea, vomiting, and blurred vision. Fetal bradycardia may occur and may be treated with terbutaline [9]. Standard treatment for possible myocardial infarction and stroke is the same as that for a nontoxic cause.

Oxytocin can cause fetal toxicity manifested by bradycardia, brain damage, neonatal jaundice, retinal hemorrhage, hypoxia, and death. In the mother, cardiac arrhythmias, hypertension, seizures, and the syndrome of inappropriate secretion of antidiuretic hormone (SIADH) have been reported [9]. Treatments for oxytocin toxicity include ritodrine to reverse oxytocin-induced labor and benzodiazepines for seizures. Because of the

Fig. 2 Chemical structures of folic acid (a) and methotrexate (b). The positions at which methotrexate differs from folic acid are shaded

Fig. 3 Simplified diagram of the action of methotrexate (MTX) on thymidylate synthesis. Tetrahydrofolate polyglutamate [FH₄(glu)_n] functions as a carrier of a one-carbon unit, providing the methyl group necessary for the conversion of 2'-deoxyuridylylate (DUMP) to 2'-deoxythymidylylate (DTMP) by thymidylate synthetase.

This one-carbon transfer results in the oxidation of FH₄(glu)_n to the dihydrofolate form FH₂(glu)_n. DHFR, dihydrofolate reductase (From Rang HP, Dale MM, Ritter JM, Gardner P: Pharmacology, 4th ed. New York, Churchill Livingstone, 2001, p 676 – with permission)

possibility of SIADH, serum sodium should be monitored.

Prostaglandins can cause tachycardia, hypertension, hyperthermia, chills, cramping, and possibly hypotension. In a case report, a 31-year-old woman of 35 weeks' gestation was administered 40 mg, instead of 1–5 mg, of prostaglandin F_{2α}

inadvertently by intramyometrial injection to improve the contractility of the lower segment of the uterus after oxytocin failed to stop uterine bleeding. Three to four minutes after injection, she had no palpable blood pressure but was resuscitated successfully with intravenous fluids, red blood cells, and dopamine [175].

Tocolytics are medications that are used to relax the uterus. These agents include magnesium, terbutaline, nifedipine, ritodrine, and indomethacin. Excluding magnesium, terbutaline is one of the more toxic agents in overdose. When comparing ritodrine, hexaprenaline, betamethasone, and terbutaline in mongrel dogs, terbutaline was found to be the most toxic [176]. Terbutaline overdose can lead to tremor, dizziness, palpitations, myocardial ischemia, and blood pressure changes [177]. Propranolol has been advocated as an antidote in a single case report but has not been studied formally [178]. Terbutaline can cross the placenta and cause injury to the fetus. Three out of the four newborns in a quadruplet pregnancy developed bradycardia, metabolic acidosis, poor tissue perfusion, and decreased urine output after 50 days of terbutaline therapy (total of 200 mg) to prevent labor [179]. It was suggested that the β_2 -receptors were downregulated by the prolonged therapy. All three neonates responded well to dobutamine administration.

Calcium channel antagonists are used widely for control of hypertension and tocolysis. The long-acting preparations seem to be safe and effective when used in these settings. When nifedipine has been administered with magnesium, however, severe hypotension has been described [180]. This association between magnesium and short-acting calcium channel blockers also has been studied in rhesus monkeys and Sprague–Dawley rats. The results support the findings in the human case reports [181, 182]. Treatment of calcium channel antagonist toxicity is described in detail in the chapter on these agents.

Ritodrine shares a similar toxicity with terbutaline because of its β_2 -agonist properties, and ritodrine toxicity is treated in a similar fashion. Indomethacin may cause gastric irritation, ulcers, heartburn, and GI bleeding in the mother. In the fetus, it may cause premature closure of the ductus arteriosus, neonatal anuria, and bowel perforation [183]. There is a case report of maternal toxic epidermal necrosis after treatment with ritodrine, indomethacin, and betamethasone [184]. Treatment of the mother after indomethacin toxicity is

supportive, whereas the treatment of the fetus is primarily preventive.

Indications for ICU Admission

- For any given poisoning, the indications for ICU admission do not substantially change with pregnancy and should be based on the mother's hemodynamic parameters.
- Physiologic changes in pregnancy, such as tachycardia and dilutional anemia, should be accounted for when making level of care triage decisions. Prenatal care records, when available, can be helpful in establishing the patient's baseline during this pregnancy.

Key Points

- When treating pregnant patients, both mother and fetus must be considered.
- In general, the best treatment for the mother will also be the best treatment for the fetus.
- The risk of teratogenicity from any acute overdose or antidotal therapy is likely very low.
- The literature on poisonings in pregnancy is sparse at best, typically based on case reports.
- After acetaminophen overdose the fetal liver may not produce significant quantities of NAPQI due to immature hepatic enzymes. However, to prevent maternal toxicity oral or IV NAC should be started, ideally within 8 h of ingestion.
- The fetus is more vulnerable and unable to eliminate salicylates as well as the mother so aggressive enhancement of elimination is warranted at potentially lower maternal serum salicylate concentrations.
- Do not hesitate to administer deferoxamine because of fears of teratogenicity in the pregnant patient. The benefits of maternal survival outweigh the risks of fetal injury.
- Treat the pregnant patient with CO poisoning longer with normobaric oxygen than would

(continued)

be indicated for a nonpregnant patient. The role of hyperbaric oxygen therapy is inconclusive. Consultation with a medical toxicologist or, if one is not available, with a poison control center is warranted.

- Hydroxycobalamin is the current treatment of choice for cyanide poisoning in the pregnant patient.
- The benefit of treating seizures from cocaine toxicity with benzodiazepines outweighs the risk of teratogenicity.
- Use the lowest effective dose of naloxone, and titrate as needed, to reverse respiratory depression and hypoxia and avoid withdrawal symptoms.

In 2010, it was estimated that approximately 13% of the US population was older than age 65 years [1, 2]. This age group is considered the fastest growing population in the United States and is expected to increase to 21% by 2040 [3]. In the United States, 81% of patients over the age of 65 take at least one prescription medication, 42% take at least one over-the-counter medication, and 29% take five or more prescription medications [4]. The number of drugs prescribed per patient is related to the number of the patient's chronic medical conditions, which directly relates to age of the patient [4]. With each new drug an elderly patient uses, the opportunity for untoward events increases [5].

Data collected for the year 2014 by the American Association of Poison Control Centers' National Poison Data System (NPDS) for human exposures to pharmaceutical and nonpharmaceutical agents showed that although exposures occurring in individuals 60 years old or older represented only 8% of the approximately two million exposures reported for the year, the poisoning fatality rate within this age group accounted for 25.8% of the total fatalities reported [6]. These findings are similar to those reported previously regarding the epidemiology of poisoning in the elderly [7, 8]. Of the 302 fatalities reported for the older age group, 25% were deemed to have resulted from suicidal exposure, whereas more than half were attributed to poisoning by one or more pharmaceutical agents [6]. Of 249 deaths that occurred in this age group linked

This is an update of a chapter originally written by Kevin L. Wallace and Anthony Morkunas in the first edition of this text.

to pharmaceutical agents, 18% were judged to have occurred as a result of therapeutic error or as an adverse reaction to therapy. It is likely that the NPDS data profoundly underestimate the morbidity and mortality of adverse drug effects in this age group.

It is conventional medical wisdom that the frequency of adverse drug-related events (ADEs) in the elderly, including medication errors and adverse drug reactions, is a function of the number of medications used per patient [9]. In a study of patients presenting to ambulatory care settings, 13.5 million ADE-related visits occurred during the 2-year study period, and a notably positive exposure–effect relationship was observed between number of medications taken and frequency of ADEs [10]. Approximately 0.5% of all ambulatory care visits were ADE related, with patients over age 65 at the highest risk. Medications most frequently associated with ADEs were nonsteroidal anti-inflammatory drugs (NSAIDs), antibiotics, anticoagulants, diuretics, hypoglycemics, β -blockers, calcium channel blockers, or chemotherapeutic agents. A relationship also has been observed between the number of drugs prescribed and the number of diseases per patient and rate of hospitalization.

General Themes in Geriatric Pharmacology and Toxicology

The elderly have:

1. Age-related changes in physiologic/pharmacologic parameters
2. A high prevalence of chronic medical disorders
3. Frequent polypharmacy, associated with medication errors, adverse effects, and drug interactions

Drug-related problems in hospitalized patients, many of whom are elderly, are associated with increases in patient morbidity, length of hospital stay, and economic costs. The costs of medication errors alone have been estimated at greater than \$3500 per adverse drug event in community hospitals, with an average associated increase in

length of hospital stay of approximately 3.1 days [11].

Pharmacology and Pathophysiology

The impact of advanced age on risk of toxic pharmaceutical or nonpharmaceutical exposure may be characterized in terms of several categories of determinants: (1) physiologic factors, such as age-related alteration in drug absorption or effect on myocardial function; (2) interactions among pharmaceutical and nonpharmaceutical agents resulting from the use of multiple medications for multiple medical problems; and (3) extrinsic, social, and behavioral factors, such as physician prescribing practice and patient compliance. The pharmacologic or toxicologic effects of exposure to a drug or other substance commonly are distinguished on the basis of whether they concern (1) the pharmacokinetic or toxicokinetic response to exposure (i.e., the disposition of that substance as a function of its absorption, distribution, metabolism, and elimination) or (2) the pharmacodynamic or toxicodynamic response (i.e., organ/system effects that result from the actions of a drug or other exogenous substance at tissue/organ effectors (e.g., cell membrane receptors, enzymes, or other components with cell signaling functions)).

The combination of age-related pharmacokinetic and pharmacodynamic changes and inappropriate exposure to drugs or other substances results in an increase in the incidence of untoward exposure events in older individuals. This increase is particularly true of pharmaceutical agents with narrow therapeutic indices (i.e., low therapeutic-to-toxic ratios), such as aminoglycosides, digoxin, lithium, metformin, phenytoin, salicylates, and theophylline. For many of these agents, their already low therapeutic index is reduced further by physiologic changes in the geriatric population. For example, older patients are at heightened risk of developing lithium toxicity with therapeutic use because their natural decline in renal function reduces their ability to excrete the drug. Iatrogenic events have a prominent causal role in mortality and

Table 1 Types of drug-related iatrogenic disease

Predictable effects of a medication based on the known pharmacologic action (e.g., tardive dyskinesia with metoclopramide)
Hypersensitivity reactions (e.g., penicillin-induced anaphylaxis)
Idiosyncratic (non-dose related) reactions (e.g., NSAID-induced aseptic meningitis)
Overlapping pharmacology (e.g., anticholinergic toxicity from concomitant use of antihistamines and antidepressants)
Adverse effects related to metabolites (e.g., myoclonus and seizures secondary to accumulation of the meperidine metabolite normeperidine)
Drug interactions (e.g., inhibition of theophylline metabolism by cimetidine)
Inappropriate dosing (e.g., failure to adjust aminoglycoside maintenance dose for age-related decline in renal function)
Medication error (e.g., dispensing error based on similarity of drug names such as Celexa (citalopram) and Celebrex (celecoxib))

morbidity from pharmaceutical exposure in all populations, but particularly in the elderly. Some types and examples of iatrogenic-poisoning occurrences are listed in Table 1. For the reasons already described, the elderly population is at increased risk for all of these errors.

Pharmacokinetic Considerations

Much of the published data regarding pharmacokinetic characteristics of various drugs are based on volunteer studies in young, healthy individuals. Age-related physiologic changes may alter drug disposition significantly in elderly patients (Table 2) and should be considered in the prevention and treatment of toxicologic illness in elderly patients.

Several well-known, age-related changes within the gastrointestinal tract have been described. Increases in gastric pH and gastric emptying time have been observed along with decreases in gastrointestinal blood flow and mucosal absorptive surface area [12]. Despite these alterations, the extent of drug absorption typically does not change; however, there may be a significant decrease in the rate of absorption

Table 2 Pharmacokinetic considerations in the elderly

Parameter	Age-related change	Impact
Absorption		
Gastric pH	Increased	Reduced absorption (e.g., itraconazole)
Gastric emptying	Reduced	Reduced rate of absorption
Distribution		
Body fat	Increased	Increased Vd for lipophilic agents (e.g., diazepam)
Body water	Reduced	Reduced Vd for hydrophilic agents (e.g., lithium)
Plasma protein		
Albumin	Reduced	Increased free fraction (e.g., phenytoin)
α -Glycoprotein	Increased (illness)	Reduced free fraction (e.g., lidocaine)
Metabolism		
Hepatic mass/blood flow	Reduced	Reduced clearance (e.g., lidocaine)
Phase I enzyme activity	Reduced	Reduced clearance (e.g., diazepam, meperidine)
Elimination		
Liver metabolism	Reduced	Reduced elimination rate
Renal excretion GFR	Reduced	Reduced elimination rate

GFR glomerular filtration rate, Vd volume of distribution

of some drugs. The net effect of these changes is hard to predict and does not allow for broad generalization, but with slowed absorption, there may be a slower onset of action for some drugs. This effect is particularly important for agents such as analgesics or sedatives, in which a rapid onset of drug effect is desirable. In addition, drugs that require an acidic environment for dissolution and absorption, such as ketoconazole or itraconazole, may be less bioavailable in the elderly.

Age-related changes in chemical, drug, or toxin distribution result from several factors. Reduction in body water and muscle mass along with an increase in body fat results in reduced volume of distribution (Vd) for substances that primarily distribute in water or lean body mass,

such as digoxin and ethanol, whereas V_d is expanded for substances that distribute primarily in fat, such as diazepam. The time interval from first administration to attainment of steady state and the elimination half-life of a substance may be increased or reduced in elderly individuals depending on whether the substance is lipid soluble or water soluble. In elderly individuals started on regular doses of a fat-soluble drug such as diazepam, the onset of toxic effects may be delayed, and their duration prolonged.

Serum albumin levels decline as a result of aging, disease, debilitation, and poor nutrition [1]. This change results in an increase in active, unbound fractions of drugs with characteristically high binding affinity to plasma proteins (e.g., salicylate, diazepam, warfarin, phenytoin, quinidine, theophylline), and an increase in the V_d . Under conditions of increased physiologic stress (e.g., acute myocardial infarction), the production and plasma content of α -acid glycoprotein (α AG), an acute-phase reactant, may be increased. The effect of an increase in α AG level in plasma is opposite to that of hypoalbuminemia (i.e., reduction in free drug fraction and amount of drug (e.g., lidocaine) available for target organ effect). These effects do not offset each other, however, because the drugs that bind to albumin frequently are different from the drugs that bind to α AG. Other disease states that are relatively common in elderly patients (e.g., sepsis) are associated with increased capillary permeability. This physiologic action may result in a dramatic increase in V_d of substances (e.g., gentamicin) that distribute into extracellular body water, requiring increased doses to maintain therapeutic blood levels.

The metabolism of a pharmaceutical or nonpharmaceutical compound may inactivate it (e.g., lidocaine), activate it (e.g., enalapril and several other angiotensin-converting enzyme inhibitor prodrugs), or prolong its activity (e.g., diazepam's conversion to its longer-acting metabolite nordiazepam). The body's clearance of some drugs (e.g., lidocaine, propranolol) greatly depends on hepatic metabolism and on hepatic blood flow or enzyme activity. Aging-related declines in liver mass and cardiac output are associated with reduction in hepatic blood flow by

50% in individuals older than age 65, resulting in slowed metabolism of perfusion-dependent drugs (e.g., lidocaine) [10]. Diseases such as congestive heart failure may compromise hepatic blood flow and clearance of perfusion-dependent drugs further.

Although experimental evidence suggests that their role, independent of other risk factors, in reduced drug clearance in elderly patients is relatively minor [11], oxidative (phase I) enzymes that make lipid-soluble drugs more water soluble for excretion by the kidney may have reduced activity in the elderly. This reduced activity may result in reduced metabolism of active parent compounds (e.g., diazepam) and, in some instances, their active metabolites (e.g., nordiazepam). Age-related reduction in phase I enzyme activity may be compounded further by non-age-related genetic variation and exogenous influences, such as drugs (e.g., erythromycin) and dietary sources (e.g., grapefruit juice), that inhibit enzyme activity. Phase II reactions, involving attachment of large polar groups (e.g., glucuronide moiety) to drugs (e.g., lorazepam), inactivating them, and further facilitating their excretion, seem to be affected minimally by aging. Drugs that normally are highly protein bound (e.g., phenytoin) may be subject to increased metabolism in the elderly as a result of the age-related decline in production of albumin and resultant increase in free drug available to the liver to be metabolized.

Perhaps the most important age-related physiologic determinant of ADEs is decline in renal clearance. Progressive diminution in renal perfusion, glomerular filtration, and tubular function commonly results in reduced clearance rates and potentially toxic accumulation of drugs or other exogenous substances. Most notable are agents that are highly dependent on renal elimination (e.g., lithium, digoxin, metformin, baclofen, normeperidine, aminoglycosides, penicillin). Serum creatinine levels may remain normal as creatinine production declines because of age-related reduction in muscle mass in parallel with decline in renal function. Estimates of renal function in elderly individuals that are based on serum creatinine level, including estimates that take age, weight, and gender into account, should

be viewed with caution and not overly relied on to assess renal-dependent drug clearance [13].

Important Geriatric Pharmacokinetic and Pharmacodynamic Characteristics

The elderly have:

1. Altered drug/toxin distribution (increase or decrease in volume of distribution) of drugs depending on fat and water solubility and protein-binding affinity
2. Reduced hepatic clearance of perfusion-dependent and phase I enzyme-metabolized substances
3. Reduced elimination of drugs predominantly cleared by the kidney
4. Increased sensitivity to target organ/tissue effects
5. Reduced ability to compensate for the pathophysiologic effects of toxic exposure (age-related blunting of homeostatic control mechanisms or pathology associated with concurrent disease or both)

Pharmacodynamic Factors

Many pharmacodynamic factors are thought to influence the elderly individual's response to exposure to pharmaceutical and nonpharmaceutical agents. These factors include age-related changes in receptor tissue density, reduced capacity for compensatory response to physiologic change or stress, blunted homeostatic control (e.g., thermoregulatory and baroreceptor) mechanisms, and altered sensitivity to the effects of various agents, independent of their pharmacokinetic characteristics [14]. Data from experimental and clinical studies show significant age-dependent reduction in β -adrenergic receptor responsiveness to agonists and antagonists [1, 4]. In general, however, elderly patients seem to be more sensitive than younger individuals to developing the adverse effects of various medications, including cognitive dysfunction (e.g., sedative agents), respiratory depression (e.g., opioid analgesics), dysrhythmia or conduction

disturbance (e.g., digoxin, calcium channel blockers), postural hypotension (e.g., tricyclic antidepressants), gastrointestinal bleeding (e.g., NSAIDs), constipation (e.g., opioid analgesics), urinary retention (e.g., antihistamines), hyponatremia or hypokalemia (e.g., thiazide diuretics), hyperkalemia (e.g., trimethoprim), hypoglycemia (e.g., ethanol), renal failure (e.g., NSAIDs), and coagulopathy (e.g., warfarin).

Preexisting or comorbid medical conditions frequently amplify the elderly patient's sensitivity to the effects of various pharmaceutical and nonpharmaceutical agents. This familiar observation is well supported by marked age-related increases in the prevalence of medical disorders such as various types of senile dementia, Parkinson's disease, hypertension, coronary artery disease, sick sinus syndrome, atrophic gastritis, prostatic hypertrophy, diabetes mellitus, hypothyroidism, malnutrition, sepsis, various malignant neoplastic diseases, and glaucoma.

Drug-Drug, Drug-Food, and Drug-Lifestyle Interactions

Toxic pharmacokinetic and pharmacodynamic interactions among various pharmaceutical and nonpharmaceutical (e.g., dietary) agents may be more likely to occur in elderly individuals, given their tendency to use multiple medications and their increased sensitivity to the effects of many agents. A vigilant posture should be assumed in regard to rapid onset, life-threatening drug-drug interactions that may occur in hospitalized elderly patients with multisystemic illness for which multiple medications may seem indicated [15].

Undesirable reduction in bioavailability of some drugs may occur in response to altered gastrointestinal pH or cation content or induction of phase I enzyme activity responsible for drug metabolism. The absorption of imidazole antifungal drugs (e.g., ketoconazole) is reduced when coadministered with drugs that raise gastrointestinal pH, such as antacids or proton-pump inhibitors, whereas the presence of increased gastrointestinal concentrations of cations (e.g., Fe^{++} , Ca^{++} , Mg^{++}) associated with consumption

of iron supplements, milk, or antacids interferes with the absorption of some antibiotics (e.g., fluoroquinolones, tetracyclines). Another familiar example of a pharmacokinetic drug interaction is that involving cigarette smoking and theophylline; induction of a phase I isoenzyme involved in theophylline metabolism, cytochrome P-450 (CYP) 1A2, by polycyclic aromatic hydrocarbons in tobacco smoke is believed to be responsible for the increased clearance of theophylline observed in individuals who smoke while taking theophylline.

Increased levels and prolonged effects of drugs metabolized by hepatic phase I enzymes (e.g., warfarin by CYP 2C9 and diltiazem by CYP 3A4) may occur in response to administration of drugs (e.g., amiodarone) or consumption of foods (e.g., grapefruit juice) that inhibit the activity of these enzymes. Other mechanisms responsible for toxic drug interactions include displacement of protein-bound drug (e.g., salicylate) by other drugs with high protein-binding affinity (e.g., warfarin), impaired renal elimination (e.g., NSAID-induced, angiotensin-converting enzyme, inhibitor-induced, or thiazide-induced reduction in lithium clearance), and additive pharmacodynamic effects, such as those produced by central nervous system depressant medications (e.g., sedatives and opioid analgesics). The reader is referred to frequently updated reference sources for drug–drug interactions [16, 17].

Social and Behavioral Factors

The increased prevalence of medical disorders in older individuals predisposes them to social, behavioral, and pharmacokinetic and pharmacodynamic risks of adverse exposure to pharmaceutical and nonpharmaceutical compounds. As previously noted, ADEs in this age group are related to individuals' tendency to use multiple medications. The causal basis for polypharmacy in the geriatric population seems to be multifactorial, involving not only an increased number of diagnoses but also deficiencies in health-care professionals' education, attitudes (e.g., neglect), and prescribing practices (e.g., off-site management of

nursing home patients, “standing” and “continuation” medication orders, tendency to add “blindly” to list of medications prescribed by other providers).

Iatrogenic medication errors (improper prescription, distribution, or administration) are an important cause of ADEs in all populations, but especially the elderly. The rates of medication error-related adverse drug events have been reported to range from 4.4% to 8.5% [18, 19]. The potential for therapeutic misadventure is compounded further by patient noncompliance, which may be intentional (e.g., on the basis of affective disturbance) or unintentional (e.g., on the basis of cognitive or perceptual dysfunction), resulting in subtherapeutic and supratherapeutic dosing.

Studies have shown up to 50% of elderly patients receive potentially inappropriate medications, with benzodiazepines, NSAIDs, diuretics, antidiabetic medications, theophylline, opioids, and aspirin among commonly prescribed high-risk medications [20, 21]. Inappropriate prescribing contributed to hospital admissions in 27% of patients and was associated with an increased risk of falls and fractures [20].

Clinical Presentation

Health-care providers must be alert to the possibility that poisoning in the elderly individual may present in a manner that is chronic or subacute, subtle (e.g., mild sleep disturbance or intermittent decline in sensorium), indirect (e.g., fall or motor vehicle accident), or atypical compared with that seen in younger healthy individuals (e.g., focal neurologic abnormality). Obtaining an accurate history, with particular attention to prescribed, recently administered, or available medications or other health supplements, is paramount in making an accurate diagnosis and embarking on effective treatment for elderly individuals. The clinician's index of suspicion for a toxicologic basis for the presenting sign and symptom complex should be raised by the documented or suggested use of medications with low therapeutic indices (e.g., digoxin), preexisting disorders (e.g.,

dementia, depression, alcoholism, renal insufficiency), or history suggesting toxic exposure to nonpharmaceutical agents (e.g., ethanol, pesticides, carbon monoxide).

Key Points in the Clinical Presentation of Geriatric Poisoning

1. Poisoning in a geriatric patient is often chronic, subacute, or subtle.
2. Neurobehavioral dysfunction is common.
3. Also relatively commonly occurring or life-threatening are cardiac dysrhythmia/conduction disturbance, postural hypotension, respiratory failure, pulmonary edema, gastrointestinal dysmotility, urinary retention, hypoglycemia, or bleeding diathesis.

Elderly individuals are particularly vulnerable to the neurobehavioral effects of a broad array of pharmaceutical agents (Table 3; refer to specific chapters on relevant drug class (e.g., antihistamine) or toxic syndrome (e.g., anticholinergic poisoning) for detailed descriptions of the neurobehavioral and other systemic effects of the pharmaceutical agents of interest) [22]. Cognitive disturbance is a common presentation for poisoning in older patients. Delirium occurs in up to 40% of hospitalized elderly patients [23]. Medications, especially benzodiazepines or neuroleptics, are highly associated with increased delirium risk.

Evaluating health-care providers should examine elderly patients with altered mental status for relatively common toxic syndromes. Anticholinergic poisoning (see ► Chap. 23, “Anticholinergic Syndrome”) is associated with the use of many prescription and nonprescription medications, including tricyclic antidepressants, first-generation antihistamines, some antiarrhythmics, antiparkinsonian agents, antipsychotics, and muscle relaxants. Alcohol or sedative-hypnotic drug intoxication or withdrawal also produces mental status changes. A high index of suspicion for chronic salicylism should be maintained in elderly individuals who present with altered sensorium and a characteristic mixed acid–base disturbance (see ► Chap. 63, “Salicylates”). Delay in diagnosis of geriatric

Table 3 Examples of drug classes/drugs that may induce neurobehavioral dysfunction^a in the elderly

Class	Specific drugs
Antiarrhythmics	Digoxin, lidocaine, procainamide
Anticonvulsants	Phenytoin, carbamazepine, valproic acid
Antidepressants	Amitriptyline, fluoxetine
Antiemetics	Promethazine, metoclopramide
Antihypertensives	Clonidine, propranolol, verapamil
Antimicrobials	Penicillin, ciprofloxacin, isoniazid
Antiparkinsonians	Levodopa, amantadine
Antipsychotics	Thioridazine
Bronchodilators	Theophylline
Antineoplastics	Methotrexate, vincristine, procarbazine, cytarabine
Histamine receptor (H ₁ -, H ₂ -) antagonists	Diphenhydramine, cimetidine
Immunosuppressants	Corticosteroids, cyclosporine
Mood stabilizers	Lithium
Muscle relaxants	Carisoprodol, cyclobenzaprine, orphenadrine
Nonsteroidal anti-inflammatory drugs	Salicylate, mefenamic acid
Opioid analgesics	Meperidine/normeperidine
Sedative–hypnotics	Diazepam, phenobarbital, meprobamate

^aRefer to specific chapters on relevant drug class (e.g., antihistamine) or toxic syndrome (e.g., anticholinergic poisoning) for detailed descriptions of the neurobehavioral and other systemic effects of the pharmaceutical agents of interest

salicylate poisoning is common, in part, because of its similarity to other disease processes [7]. Preexisting chronic or acute drug (e.g., NSAID induced) renal insufficiency may be an important contributing factor to the development of neurotoxicity, including seizures, from renally eliminated drugs, such as lithium and certain antibiotics particularly among the fluoroquinolone (e.g., ciprofloxacin) and β -lactam antibacterials (e.g., penicillin, imipenem, cefazolin) [24].

Clinicians also should recognize that elderly individuals with underlying disorders such as atherosclerotic cerebrovascular disease may be more sensitive to insults such as sulfonyleurea-induced

or alcohol-induced hypoglycemia [25]. Acute-onset focal neurologic deficits may be more likely in elderly patients than in younger healthy individuals to represent the potentially reversible effects of a toxic insult, as opposed to progression of the primary disease process.

Although they are nonspecific, vital sign abnormalities that are more likely to occur in elderly individuals in response to a toxic insult include hyperthermia and hypothermia, orthostatic hypotension, and bradycardia. The reported prevalence of orthostatic hypotension in the geriatric population is up to 32% [26] and frequently is associated with the use of medications such as diuretics, calcium channel blockers, β -blockers, angiotensin-converting enzyme inhibitors, nitrates, antidepressants, and antipsychotics.

Presyncopal dizziness or frank syncope may reflect cardiac rhythm or conduction disturbance as an acute or chronic toxic effect of administration of drugs that directly (e.g., β -blockers, calcium channel blockers) or indirectly (e.g., digoxin) prolong atrioventricular nodal conduction, increase automaticity (e.g., digoxin), or cause repolarization abnormalities such as QT interval prolongation (e.g., type IA antidysrhythmics, tricyclic antidepressants, piperidine antipsychotics such as thioridazine and mesoridazine, and the newer atypical neuroleptics). Extracardiac manifestations of digoxin toxicity, such as anorexia, nausea, visual disturbance, and confusion, may support the diagnosis further but are so prevalent and nonspecific that their presence may not enhance clinical recognition [27].

Pulmonary edema is more likely to occur in elderly individuals as a consequence of drug-induced negative inotropy combined with limited cardiac functional reserve capacity. An acute respiratory distress syndrome may be a manifestation of poisoning (e.g., chronic salicylism) and may not be associated with the presence of jugulovenous distention or S_3 gallop, typical features of cardiac failure. Gastrointestinal dysmotility disorders (e.g., constipation, adynamic ileus) and genitourinary dysfunction (e.g., urinary distention) are relatively common clinical presentations in the elderly for toxicity from drugs

with narcotic (e.g., opioid analgesics) or anticholinergic (e.g., antihistamines) actions. The presence of a bleeding diathesis should suggest the possibility of warfarin-induced coagulopathy in individuals who have indications for or are known to be on anticoagulant treatment.

Diagnosis

Although there is no substitute for a thorough and accurate history in making a timely diagnosis of poisoning in an elderly individual, the clinical laboratory can be of invaluable assistance to the clinician dealing with initially scant or unobtainable historical information. The limitations and caveats that apply to toxicologic analyses in general apply to their role in the diagnosis and management of geriatric poisoning. Correlations between drug levels and the occurrence of toxicity may be even more limited in elderly patients, given their propensity to present well into the post-distribution phase after chronic, cumulative exposure to potentially toxic agents (e.g., salicylate, theophylline, digoxin, lithium) and their aging-altered drug distribution (e.g., increased free phenytoin fraction).

Routine clinical laboratory monitoring of serum electrolytes, glucose, and indices of renal function may be essential to the diagnosis and further prevention of untoward medication effects (e.g., digoxin-induced arrhythmia) in high-risk elderly patients, such as patients on diuretic or oral hypoglycemic therapy. Clinically significant abnormalities of serum sodium and potassium are particularly common among elderly individuals taking thiazide diuretics (hyponatremia, hypokalemia), whereas angiotensin-converting enzyme inhibitors, potassium-sparing diuretics, and trimethoprim may cause hyperkalemia [28, 29]. As previously discussed, methods used to estimate drug clearance by the kidney that are based on serum creatinine should take into account age-related changes in muscle mass and creatinine excretion and otherwise be employed with caution.

In contrast to serum chemistry indices of renal function, quantitative serum values of hepatic

enzymes (e.g., transaminases) and liver function tests (e.g., prothrombin time) are of little predictive value with regard to drug clearance. These analyses are used mainly to detect and monitor toxic hepatocellular injury (e.g., acetaminophen-induced hepatic necrosis) and effects on hepatic synthetic function (e.g., inhibition of vitamin K-dependent clotting factors by warfarin or salicylate). Quantitative serum drug assays are generally indicated if there is any clinical suspicion in elderly patients of salicylate or acetaminophen poisoning or for therapeutic monitoring of drug therapy involving agents with narrow therapeutic indices (e.g., digoxin, theophylline, lithium, aminoglycosides). Apart from routinely obtaining admission electrocardiograms and chest radiographs on all elderly patients requiring hospitalization for management of poisoning, indications for other diagnostic tests, such as abdominal radiographs and blood lead level, depend on the specific exposure.

Treatment and Prevention

Treatment of acute and chronic poisoning in elderly patients should be approached in much the same manner as for other age groups, with many added caveats that pertain to age-related pharmacokinetic and pharmacodynamic differences. Special attention should be directed at the potentially greater need for aggressive ventilatory support and for caution in fluid volume resuscitation in elderly individuals, given their greater sensitivity to the central depressant effects of some agents, greater likelihood of cardiac inotropic or chronotropic compromise, and tendency to develop life-threatening complications of such therapy (e.g., acute pulmonary edema). Clinicians also should recognize in older patients with chronic medical conditions the importance of considering blunted homeostatic (e.g., thermoregulatory) mechanisms, endocrine dysfunction (thyroid, adrenal), and nutritional deficiencies (e.g., limited vitamin and glucose stores) and address these with appropriate supportive measures (e.g., body warming or cooling, empirical thiamine administration). Although it may seem

obvious, a frequently overlooked step in the initial management that may be of significant short-term or long-term benefit is temporary discontinuation of previously prescribed medications, particularly medications with narrow therapeutic indices or medications considered likely offenders (e.g., lithium, warfarin, digoxin, NSAIDs, anticholinergics, and serotonergic drugs).

Hemodialysis as a method of enhanced elimination of drugs and toxins (see ► [Chap. 12, “Extracorporeal Substance Removal”](#)) plays an important role in the management of geriatric poisoning, particularly in instances in which the offending agent is of low molecular weight, low Vd, and low protein-binding affinity and undergoes predominantly renal elimination (e.g., lithium, salicylate, phenobarbital). The greater likelihood of impaired renal drug clearance and susceptibility to complications from aggressive sodium and fluid loading in this age group provides a compelling argument in support of hemodialysis when it is indicated for toxicologic reasons.

Key Points in the Management of Geriatric Poisoning

1. Medication history should be reviewed carefully for evidence of medication error, adverse effect, or drug interaction, and potentially offending medications should be discontinued.
2. Extra caution should be exercised during administration of supportive and antidotal therapy, urinary pH manipulation, and gastrointestinal decontamination.
3. Hemodialysis as a means of enhancing elimination may be warranted further in poisoned elderly individuals, given their age-related reduction in renal clearance or increased risks of other therapy.

In older individuals, caution also should be exercised in the administration of antidotal agents such as physostigmine for anticholinergic poisoning in individuals at risk for cardiac conduction disturbance, antidigoxin antibodies for digitalis poisoning in patients with preexisting rapid atrial

fibrillation, β -adrenergic antagonists for theophylline-induced tachydysrhythmias in individuals who may have underlying coronary artery or obstructive airway disease, and flumazenil for suspected benzodiazepine-induced central nervous system depression in individuals at risk for acute withdrawal from the latter agents. Antidotal agents that are cleared primarily by the kidney (e.g., the heavy metal chelator calcium sodium ethylenediamine tetraacetic acid) may be ineffective or contraindicated in individuals with renal insufficiency. Similarly, the dosing of medications used to treat complicating or concurrent illness that is eliminated primarily via the renal route (e.g., aminoglycoside antibiotics meperidine/normeperidine) should be adjusted for renal insufficiency. Although the administration of an antidote in many of these circumstances still may be warranted, consultation with a medical toxicologist is recommended.

Prevention of toxic exposure in hospitalized elderly patients may be enhanced further through improved health-care provider education, limited use or avoidance of certain pharmaceutical agents, computerized physician entry of medication orders, and pharmacy surveillance (computerized or on-site, pharmacist staffed) [22, 30, 31].

Epidemiology

According to the National Poison Data System (NPDS) of the American Association of Poison Control Centers, in 2014 poisoning in children under the age of 20 accounted for 61% of calls to poison centers in the United States [1]. The proportion of those cases that required referral to a health care facility (HCF) varied. 12.7% of children ≤ 5 years and only 16.5% of children between 6 and 12 years were managed in an HCF compared to 61.1% of teenagers (13–19 years). The proportion of children described as having a “Major Effect” rose from 0.07% in the under 5 age group to 1.65% in teenagers. The fatality rate was highest in the teen group (0.05%), where more than one half of ingestions are intentional versus the under 5 age group ($<0.002\%$) where 99.5% of exposures are unintentional. The number of pediatric deaths among cases reported to US poison centers was 88. These figures have remained consistent over the past several years.

While the number of patients requiring pediatric intensive care unit (PICU) admission is unclear, in a European study 1.5% of patients seen for poisoning in an emergency department (ED) were admitted to the PICU [2]. In a Canadian study, 6.3% of patients seen in a metropolitan pediatric ED with poisoning were admitted to the

PICU [3]. This represented 3.1% of all PICU admissions to that institution over the 3-year study period. In a US retrospective study, 8% of all PICU admissions to an academic center represented poisonings [4]. According to NPDS, 127 children received hemodialysis, 2336 received mechanical ventilation, 509 received vasopressors, and 21 received extracorporeal membrane oxygenation (ECMO) in the USA in 2014.

It should be noted that the number of poisoning exposures and the number of deaths described in NPDS underrepresent the actual nationwide numbers as not all cases are reported to poison centers.

Admission to the PICU

Critically ill pediatric patients should be cared for in a PICU where there are specially trained personnel and equipment tailored to the needs of children. If there is no PICU, unless clinical effects are mild to moderate, and the expected duration of illness is short, arrangements should be made to transfer the patient to a PICU for care. Most tertiary care programs, and some smaller ones, have dedicated pediatric transport teams for the movement of patients. These teams may have various compositions and may include pediatric nurses, respiratory therapists, and physicians. They typically use specially outfitted ambulances that contain pediatric equipment and are equipped to handle emergencies during transport. It is likewise important to have the expertise of a consultant medical toxicologist ideally on site, or through the regional poison center.

Indications for admission to the PICU are given in Table 1. In the triage of patients with few, or no, clinical manifestations of their poisonings, it is important to carefully consider the time of exposure and the pharmacokinetics of the agent in question so patients can be observed in the critical care setting until the risk of serious compromise has passed. Finally, patients at high risk of suicide may be admitted to the PICU if no other closely monitored area is available.

General Pediatric Intensive Care Unit Treatment

The usual mechanism of admission to the PICU is either through the ED or via transfer from another institution. Decontamination, if any, is typically initiated in the referring facility prior to transfer. In most cases, the time elapsed prior to PICU admission renders further decontamination efforts relatively useless after admission. Potential exceptions include techniques such as whole bowel irrigation for selected toxins, such as controlled-release products, iron, lithium, and potassium, or in body packers [5]. Multiple dose activated charcoal may also be considered in certain toxic ingestions (see “► Chap. 3, “[Therapeutic Approach to the Critically Poisoned Patient](#)” for detailed discussion) [6]. Whole bowel irrigation and multiple dose activated charcoal should be administered with caution, or not at all, in patients with ileus or circulatory shock.

The mainstay of the ICU management of a poisoned pediatric patient is supportive care. The general ICU care of most poisoned patients is not any different from the care received by other ICU patients with a comparable level of severity and similar symptoms [7, 8]. All PICU patients should have continuous monitoring of heart rate, respiratory rate, and pulse oximetry. The frequency of nursing assessment and vital signs monitoring depends on the stability of the patient and the problems present or anticipated. The frequency of assessment may vary from every few minutes to every 4 h and should be appropriate for the patient and the circumstances.

Any patient admitted to an ICU should have stable intravenous access. Whether a peripheral intravenous catheter or a central line is required depends on the stability of the patient and the problems anticipated. If major organ system instability is present or likely, central access or multiple peripheral intravenous lines generally should be obtained. A single peripheral intravenous line is not adequate for a severely ill patient who may require lifesaving therapies. Central lines can be placed in subclavian, internal jugular, or femoral vessels. In newborns, the umbilical vein may also

Table 1 Indications for pediatric ICU admission relevant to toxic exposures

1. Acute respiratory failure as manifested by one or more of the following:
a. Need for mechanical ventilation or emergency tracheostomy
b. Marked respiratory compromise as indicated by
(1) RR ≤ 20 or ≥ 60 for infants ≤ 1 year old
(2) RR ≤ 12 or ≥ 60 for patients > 1 year old
(3) SpO ₂ $\leq 92\%$ on 100% oxygen by nonrebreather mask or tracheostomy collar
(4) PaO ₂ < 80 mmHg on 100% oxygen by nonrebreather mask
c. Rapidly progressive deterioration in respiratory status
d. Respiratory acidosis with PaCO ₂ > 60 mmHg and pH < 7.25
e. Airway obstruction
g. Apnea
h. Anaphylaxis
2. Hemodynamic instability or circulatory failure as manifested by one or more of the following:
a. Shock as indicated by
(1) Capillary refill > 4 s
(2) Nonpalpable distal or proximal pulses
(3) Systolic blood pressure $<$ lower limit for age and/or MAP < 50 mmHg (neonates < 40 mmHg)
(4) Acute metabolic acidosis with pH < 7.25 , base deficit > -10 or serum bicarbonate ≤ 10 mEq/L
(5) Need for invasive hemodynamic monitoring
b. Unstable or new cardiac dysrhythmia
c. Need for continuous infusion of vasoactive drugs
d. ECG showing changes consistent with ischemia
e. Acute congestive heart failure
f. Unstable vascular volume as indicated by
(1) Need for > 40 mL/kg fluid bolus
(2) Hemoglobin < 8 g/dL in a bleeding or hemolyzing patient
(3) Platelet count $< 20,000$ with active bleeding
(4) INR > 2 with active bleeding
g. Need for cardioversion
h. Malignant hypertension
3. Neurologic instability as manifested by one or more of the following:
a. Acute neurologic deterioration as indicated by
(1) Glasgow Coma Scale score ≤ 10
(2) Severe irritability
(3) Hallucinations
(4) Posturing
b. Intracranial hemorrhage
c. Evidence of increased ICP
d. Seizures
e. Delirium
4. Metabolic derangements placing patients at risk of serious complications as evidenced by one or more of the following:
a. Serum sodium < 125 mmol/L or > 160 mmol/L
b. Serum potassium < 3 mmol/L or > 6.5 mmol/L (nonhemolyzed)
c. Blood glucose < 30 mg/dL or > 400 mg/dL (1.7 mmol/L or 22.2 mmol/L)
d. Ionized calcium < 0.8 mEq/L
e. Base deficit > -10
5. Other patients displaying evidence of acute or developing failure of an essential organ system
6. Patients with a toxic exposure in which none of the above are present but in which
a. One of the above admission criteria can be expected to develop within a few hours based on the nature of the exposure
b. The patient is suicidal, and no other safe area of medical and psychiatric observation exists

ECG electrocardiogram, ICP intracranial pressure, INR international normalized ratio, MAP mean arterial blood pressure, PaO₂ arterial oxygen partial pressure, PaCO₂ arterial carbon dioxide partial pressure, RBC red blood cell, RR respiratory rate, SpO₂ arterial oxygen saturation

be available and can be used. If lines are properly placed in either the superior or the inferior vena cava, they may be transduced to provide central venous pressure measurement. Because improperly placed lines can give incorrect and misleading information, placement should be verified by radiograph before the lines are transduced. Arterial catheters for arterial blood sampling and continuous blood pressure monitoring should be inserted in any patient with significant cardiovascular dysfunction secondary to a toxic exposure and in patients intubated because of central nervous system (CNS) depression.

The use of laboratory monitoring, including arterial blood gas measurements, should be dictated by the status of the patient, the initial values obtained, and the anticipated problems. Sequential measurement of drug or toxin levels may be valuable in selected cases as either a marker of therapeutic efficacy or a predictor of likely toxic effects.

Neurologic Toxicity

Derangement of neurologic function associated with intoxication is a common reason for PICU admission. Common neurologic changes resulting from intoxication include a depressed level of consciousness, agitation and delirium, or seizures, sometimes in combination. A detailed discussion of these topics is beyond the scope of this chapter, but some basic issues of critical care assessment and initial management strategies are discussed. For greater detail see ► [Chap. 19, “Toxicant-Induced Alterations in Consciousness.”](#)

A diminished level of consciousness may result from a number of causes, such as intoxication, metabolic derangements, and structural neurologic insults such as trauma, intracranial hemorrhage, focal ischemic injury or stroke, infection, or psychiatric disorders. Sometimes more than one of these categories simultaneously may be responsible for mental status change, as in a patient with ethanol toxicity accompanied by hypoglycemia or a trauma patient under the influence of drugs or ethanol.

Altered mental status resulting from toxic and metabolic causes differs from mental status alteration from other causes in that brain structure is not altered, and neurologic pathways are intact. Clouding of consciousness usually is not associated with focal neurologic findings and is reflective of global encephalopathic change. Altered mental status may occur in combination with CNS depression, as in the case of benzodiazepine, opiate, or barbiturate ingestion, or with agitation and delirium, as is seen in dextromethorphan intoxication. Alternatively, agitation and delirium may occur without alteration in consciousness, as seen in anticholinergic and hallucinogenic drug ingestions, and *Centruroides* envenomation.

Physical findings on neurologic examination after ingestion of a CNS depressant (e.g., benzodiazepine, opioid, or barbiturate) usually include diminution in the magnitude of response rather than loss of response, unless the overdose is large enough to induce coma. Pupillary response generally is preserved, although commonly it is sluggish and diminished in intensity. An exception is the ingestion of antimuscarinics in which pupillary response may be absent. Toxic or metabolic encephalopathy also may result in diminution of control of brainstem functions, such as respiratory drive, resulting in hypoventilation or apnea, or control of peripheral vascular tone, resulting in vasodilation and hypotension. Loss of motor tone in skeletal musculature may result in bulbar and hypopharyngeal muscle dysfunction, causing upper airway obstruction and loss of airway protective reflexes, or may result in a decrease in respiratory muscle function, with resulting hypoventilation.

Alternatively, patients may present with altered mental status in combination with agitation, hallucinosis, and even seizures. The list of drugs that can manifest in this manner is long and includes *Centruroides* scorpion stings, antimuscarinics, amphetamines, cocaine, synthetic cannabinoids, lysergic acid diethylamide, ketamine, phencyclidine, “bath salts,” and huffing of solvents. These patients may present with hyperthermia, tachycardia, and hypertension. Motor tone is frequently increased, with associated hyperreflexia and abnormal motor movements.

The assessment of a patient with neurotoxicity includes a detailed history and physical examination to exclude other causes of neurologic deterioration. Localizing findings strongly suggest a cause other than intoxication. Computed tomography (CT) or magnetic resonance imaging of the brain may be indicated to exclude hemorrhage, stroke, global ischemic injury, or cerebral edema. Fever in the presence of depressed mental status may warrant the performance of a lumbar puncture to rule out infection, although this may represent an anticholinergic syndrome for which a trial of physostigmine may aid in making the distinction. An electroencephalogram may be warranted to rule out nonconvulsive status epilepticus.

In the child with a depressed level of consciousness, the first priority is to ensure adequate airway, breathing, and circulation. Once these have been assured, point of care measurement of blood glucose is indicated with correction of hypoglycemia if warranted. Empiric administration of naloxone is indicated. The pediatric starting dose is 0.01 mg/kg. Thiamine, although commonly administered in adults because of the relatively high incidence of deficiency associated with alcoholism or malnutrition, is not routinely indicated in children, although it may be considered in the older child where a history of alcoholism cannot be excluded.

Seizures

Seizures are a common finding in intoxication with drugs that affect the central nervous system. A detailed discussion of the neuropharmacology of seizures in poisoned patients is beyond the scope of this chapter (see ► [Chap. 20, “Toxicant-Induced Seizures”](#)). Seizure control is a primary issue in the management of a poisoned child in the PICU, however, and is addressed briefly here.

Seizures associated with ingestion of toxins may be difficult to control and may be recurrent or persistent, resulting in status epilepticus. Status epilepticus is associated with an increase in cerebral metabolic demand [9] for oxygen and may cause a decrease in respiratory effort, upsetting the

balance between cerebral oxygen demand and delivery, resulting in cerebral ischemia. Aggressive management of seizures associated with poisoning is crucial to unimpaired recovery.

The first priority in management of seizures is prompt attention to the adequacy of airway patency, respiratory effort, and oxygenation, to ensure oxygen delivery to the brain. Administration of supplemental oxygen, positioning to avoid airway obstruction, and attention to the adequacy of spontaneous respirations, with aggressive intervention in patients with marginal respiratory status, is critically important. Assessment and correction of hypoglycemia and electrolyte disturbances should also be promptly performed.

Anticonvulsant management of toxicant-induced seizures can typically be achieved with benzodiazepines. Lorazepam and diazepam appear to be equally efficacious at terminating status epilepticus in children [10] although lorazepam may have a lower rate of seizure recurrence after treatment [11, 12]. If benzodiazepines are insufficient, phenobarbital, propofol, and valproic acid are useful additional agents for seizure control. Phenytoin is unlikely to be efficacious in the treatment of toxin-induced seizures [13].

A particular cause of seizures likely to be unresponsive to traditional anticonvulsant therapy is ingestion of the antituberculous drug isoniazid and similar hydrazine compounds. Seizures in this instance result from depletion of pyridoxine and are generally responsive only to pyridoxine replacement. This specific ingestion is discussed in detail in ► [Chap. 65, “Isoniazid and Related Hydrazines.”](#)

Cardiovascular Toxicity

Cardiovascular compromise resulting from intoxication is a serious complication of poisoning that requires prompt critical care management and monitoring. A thorough understanding of the derangements produced by individual toxins and a sophisticated understanding of cardiovascular assessment, supportive care, and monitoring techniques are essential for successful treatment of

these critically ill patients. Cardiovascular function is the end result of a complex interaction between the heart and the peripheral vascular system. When functioning properly, this interaction provides for adequate cardiac output and appropriate distribution of cardiac output to specific organs and tissues to ensure optimal function. Cardiac function is regulated by specific neural and hormonal feedback mechanisms that monitor and modulate cardiac rate and contractility, peripheral vascular resistance and venous capacitance, and specific organ and tissue blood flows. A toxin may harm the heart or vascular smooth muscle directly; have neurogenic effects on the sympathetic or parasympathetic regulation of heart rate, contractility, or vascular resistance; or cause changes in intravascular volume, metabolic disturbances such as hypoglycemia, or electrolyte disturbances.

Evaluation of an intoxicated child at risk for cardiovascular compromise requires a thorough physical examination. Assessment of vital signs and autonomic findings, such as pupillary dilation or constriction, skin flushing or pallor, lacrimation, and salivation, provides useful information regarding cardiovascular status and may aid in identifying the type of intoxication. Evaluation of intravascular volume, performed by assessment of jugular venous distention, skin turgor, moistness of mucous membranes, and liver size, informs initial resuscitative management.

The adequacy of cardiac output can be assessed indirectly by the assessment of organ and tissue function. The patient's mental status, depth and frequency of respirations (increased in metabolic acidosis), volume of urine output, and estimation of peripheral perfusion (via palpation of central and peripheral pulses, capillary refill time, and peripheral warmth and skin color) reflect cardiac output. After initial assessment, reexamination at frequent intervals identifies changes in cardiovascular stability, directing further resuscitative care. Continuous cerebral and somatic oximetry using near infrared spectroscopy can provide assessment of the adequacy of cardiac output, as can serial measurement of arterial or mixed-venous lactate concentrations or mixed-venous oxygen saturation.

In addition to assessment of volume status and cardiac output, laboratory abnormalities should be addressed. Evaluation of acid–base status with arterial blood gases; measurement of electrolytes, including calcium, magnesium, and glucose; and baseline assessment of hepatic and renal function provide a basis for correction of metabolic derangements. Current technology allows for bedside evaluation of these parameters. In addition, if the intoxicant is known, plasma or serum concentrations of the intoxicating agent in selected cases may provide information regarding the severity of intoxication and aid in treatment decisions. Electrocardiography and echocardiography may also be indicated to guide therapy in cases of suspected intoxication with cardiovascular instability.

Patients requiring ICU admission for significant hemodynamic compromise and patients with a known ingestion with the potential for cardiovascular effects need cardiovascular monitoring. Critical care monitoring frequently includes placement of an arterial catheter for continuous direct measurement of blood pressure. The arterial catheter also allows painless arterial blood sampling for blood gases, enabling frequent monitoring of acid–base status and cardiorespiratory function. Placement of a central venous catheter may provide additional information about central venous filling pressures, which may be useful in decisions regarding fluid resuscitation and the use of inotropic agents. Central venous access provides for the reliable administration of cardioactive agents, such as inotropes, vasoconstrictors, and vasodilators, as needed.

Initial management of cardiovascular dysfunction is focused on restoration of cardiac output and organ system perfusion and correction of metabolic and electrolyte disturbances. Early in the course of cardiovascular instability, compensatory mechanisms may keep vital signs relatively normal. These mechanisms are an increase in sympathetic tone, resulting in an increase in heart rate, and peripheral vascular resistance may minimize changes in blood pressure, at the expense of cardiac output. Hypotension results only when the capacity of compensatory mechanisms is exceeded or when the intoxicating substance directly interferes with these mechanisms. One

example is tricyclic antidepressant intoxication, in which α -adrenergic receptor blockade interferes with peripheral vasoconstriction, while the direct cardiovascular effects diminish cardiac output. Similarly, beta blockers may blunt the tachycardic response normally seen with hypotension, similarly diminishing cardiac output.

Initial correction of inadequate cardiac output can usually be accomplished in the absence of identification of an intoxicating substance. Identification of an intoxicating substance may simplify management if the intoxicant's common effects are known, allowing specific intervention for these effects. In the absence of this knowledge, initial resuscitation involves administration of intravenous fluids to ensure adequate intravascular volume. Initial rapid administration of isotonic fluids, usually crystalloid, such as normal saline or Ringer's lactate, in increments of 20 mL/kg body weight given over 10–15 min, is used to reestablish sufficient intravascular volume. After initial fluid administration, reassessment of vital signs and physical examination are performed, and additional fluids are administered if reestablishment of intravascular volume is incomplete. Repletion of intravascular volume may result in restoration of vital signs and tissue perfusion, with improvement in mentation, urine output, and peripheral pulses. In patients in whom intrinsic cardiac function is impaired, overly vigorous expansion of intravascular volume may result in fluid overload, with an increase in liver size, evidence of pulmonary edema, jugular venous distention, or an increase in heart size on chest radiograph, without improvement in vital signs and tissue perfusion. In these patients, the addition of an inotropic agent may be necessary to improve cardiac function and tissue oxygen delivery. Bedside echocardiography may be valuable in helping to decide between the administration of additional fluid and the addition of a cardiovascular agent. The choice of inotrope or pressor for a given circumstance depends on the cardiovascular derangements present. Cardiovascular drug effects depend on the drug's site of action (e.g., α -adrenergic versus β -adrenergic effects, vasopressin receptor effects), and choosing a specific agent depends on matching the expected effects of

a drug to the hemodynamic derangement requiring correction. Although almost any agent may be administered temporarily through a peripheral intravenous catheter, the central venous route is preferred because of the risk of extravasation, particularly in infants in whom intravenous infiltration is not uncommon. Since epinephrine is commonly administered subcutaneously or intramuscularly for other indications with little in the way of local deleterious effects, it may be a good choice of initial adrenergic agent to use peripherally, particularly if the vein is small, until more reliable access can be established as it might be safer in the case of extravasation. This topic is discussed in greater detail in ► [Chap. 14, "The Assessment and Management of Hypotension and Shock in the Poisoned Patient."](#)

Dysrhythmias

A common complication of poisoning with cardiovascular agents is the development of dysrhythmias. Dysrhythmogenic drugs may produce their actions by directly affecting the electrical conduction system of the heart, by changing the electrical potential of individual myocardial cells, by indirectly influencing the cardiac conduction system via the autonomic nervous system or CNS, or by inducing electrolyte and metabolic disturbances that affect electrical activity within the heart. Table 3 lists drugs commonly associated with dysrhythmias in pediatric patients (Table 2).

Bradydysrhythmias occur as a result of agents that decrease sympathetic outflow from the CNS, such as opioids, benzodiazepines, and barbiturates, and as a result of drugs that decrease the chronotropic activity of the conduction system, including agents such as beta blockers, nondihydropyridine calcium channel blockers, and class I antidysrhythmic drugs. Severe overdose of any of these agents may result in asystole and cardiac arrest.

Treatment of bradydysrhythmia resulting from an unknown ingestant is supportive. Administration of atropine or inotropic agents with positive chronotropic effects (e.g., epinephrine) may be corrective. If the causative agent of the ingestion

Sedative-hypnotics
Tricyclic antidepressants (late or massive ingestion)
Tachydysrhythmias
α -Adrenergic agonists
Aluminum phosphide
Amantadine
Antidysrhythmics
Anticholinergics
Antihistamines
Astemizole
β -Adrenergic agonists
Carbamazepine
Cisapride
Chloral hydrate
Chloroquine
Cholinomimetics
Digitalis glycosides
Hydrocarbons/solvents – “huffing”
Inhalational anesthetics
Ecstasy (3,4-methylene- dioxymethamphetamine)
Orphenadrine
Pentamidine
Plants containing cardiac glycosides (foxglove, lily of the valley, oleander, yew)
Phenothiazines
Phosphodiesterase inhibitors (methyl xanthines, amrinone, milrinone)
Propoxyphene
Scorpion envenomation
Selenium – “gun blue”
Snake envenomation
Sympathomimetics (amphetamines, cocaine, phencyclidine)
Terfenadine
Theophylline
Tricyclic antidepressants

Table 3 Indications for endotracheal intubation

1. Upper airway obstruction nonresponsive to positioning or less invasive device
2. Depressed level of consciousness
a. Absence of gag and cough reflexes
b. Apnea/hypoventilation
3. Actual or impending respiratory failure
a. Hypoxic ($\text{PaO}_2 < 60$ mmHg or oxygen saturation $< 90\%$ on $\text{FiO}_2 > 0.6$)
b. Hypercarbic ($\text{PaCO}_2 > 50$ mmHg with $\text{pH} < 7.30$)
4. Cardiovascular instability with hypotension, inadequate cardiac output, metabolic acidosis
5. Excessive airway secretions inadequately cleared with cough/pharyngeal suctioning
6. Treatment of pulmonary hypertension
FiO_2 fractional concentration of oxygen in inspired gas, ICP intracranial pressure, PaO_2 arterial oxygen partial pressure, PaCO_2 arterial carbon dioxide partial pressure

is known, therapies directed at antagonism of the toxic effects (e.g., calcium chloride administration for calcium channel blocker overdose) may be beneficial. In severe cases of bradydysrhythmia or heart block unresponsive to pharmacologic therapy, direct transthoracic pacing or transvenous pacing may be necessary (see subsequent section).

Tachydysrhythmias are commonly seen after poisoning. Sinus tachycardia may occur as a result of increased sympathetic tone after ingestion of CNS stimulants, as a result of ingestion of agents that block catecholamine reuptake at sympathetic nerve terminals (e.g., methamphetamine, cocaine), or as a result of ingestion of drugs with anticholinergic properties. Halogenated hydrocarbons, such as chloral hydrate, may sensitize the myocardium to the effects of endogenous catecholamines, increasing the risk of tachydysrhythmias, including supraventricular and ventricular tachycardia [29, 30]. Overdose with antidysrhythmic agents, particularly class Ia agents, may result in supraventricular or ventricular tachycardia. Tricyclic antidepressants, carbamazepine, and diphenhydramine, all of which share structural similarities and have cell membrane effects similar to quinidine and other class Ia antidysrhythmics, have propensities to develop wide-complex ventricular dysrhythmias.

Torsades de pointes is a unique form of ventricular tachycardia that can be seen with certain overdoses and adverse drug reactions during therapeutic use. Torsades de pointes may occur after ingestion of any drug associated with ventricular tachycardia, such as the class Ia and class Ic antidysrhythmics. This dysrhythmia is discussed in greater detail in ► [Chap. 22, “Toxicant-Induced Torsade de Pointes.”](#)

Treatment of tachydysrhythmias associated with poisoning is generally the same as in other circumstances, with some unique exceptions. The treatment of dysrhythmias associated with a specific antidysrhythmic or class of antidysrhythmic agents should avoid using another drug in the same class. For example, the use of procainamide to treat dysrhythmias associated with quinidine overdose is contraindicated. Treatment of supraventricular tachycardia of hemodynamic significance may be benefited by the use of adenosine, although the short half-life of adenosine and the persistent presence of a dysrhythmogenic toxin make the utility of short-acting agents uncertain. The use of drugs of general utility, such as lidocaine and amiodarone, may be preferred in this setting, unless it is contraindicated on electrophysiologic grounds in specific intoxications.

A unique circumstance is seen in dysrhythmias associated with overdose of tricyclic antidepressants and other agents with sodium channel activity, such as class Ia antidysrhythmic drugs. Numerous studies have investigated the antidysrhythmic effects of sodium bicarbonate in these life-threatening overdoses. Sodium bicarbonate has been shown to consistently reverse wide-complex tachydysrhythmias associated with tricyclic antidepressant poisoning [14–16]. Studies suggest that the beneficial effects are due to both sodium loading and alkalinization [17]. Similar but less consistent reversal of dysrhythmias has occurred with sodium bicarbonate in the treatment of dysrhythmias associated with quinidine and other class Ia antidysrhythmics [18]. This topic is discussed in greater detail in ► [Chap. 39, “Sodium Channel-Blocking Antidysrhythmics.”](#)

Treatment of a pediatric patient with torsades de pointes associated with overdose is similar to that seen with torsades de pointes in any other circumstance. Correction of electrolyte and other metabolic disturbances is crucial, followed by administration of magnesium sulfate [19]. Electrical cardioversion frequently is unsuccessful in converting torsades de pointes. Magnesium sulfate is also the treatment of choice for drug-induced prolonged QT interval, although there is considerable variation among providers in determining threshold at which treatment should be given [20]. This topic is discussed in greater detail in ► [Chap. 22, “Toxicant-Induced Torsade de Pointes.”](#)

In pediatric patients with massive overdose with a cardiotoxic agent, dysrhythmias may be unresponsive to pharmacologic therapy, and electrical cardioversion may be unsuccessful or only temporarily successful in converting the patient back to a sinus rhythm. For these patients, temporary pacing may be attempted. Available methods of pacing include transcutaneous pacing, transvenous pacing, and transesophageal pacing. Transcutaneous pacing, although uncomfortable in a conscious patient, is the most readily available modality for cardiac pacing. This approach may be lifesaving while alternative therapies are initiated, such as transvenous pacing, initiation of additional pharmacologic measures, or cannulation for ECMO. Sedation and analgesia may be beneficial in alleviating the discomfort associated with external pacing.

Transvenous pacing, utilizing a catheter placed into the heart via central venous access, is an alternative to transcutaneous pacing. This modality is more technically difficult, especially in the infant or small child, requiring availability of fluoroscopic guidance for effective catheter placement, and requires more time in its placement. Adverse effects are minimal when the catheter is placed appropriately, and the transvenous approach is tolerated better by the patient and may be used for a longer time than transcutaneous pacing.

Transesophageal pacing may be useful for overdrive pacing of patients with atrial tachydysrhythmias and may also be attempted in cases of

severe symptomatic sinus bradycardia not responsive to other modalities. It generally requires anesthesia or deep sedation as well as consultation from a pediatric cardiologist experienced in the procedure. Although there are case reports of successful ventricular pacing via this method [21], transesophageal pacing cannot be relied upon in the case of AV block.

Respiratory Support

Respiratory distress and the potential for respiratory failure are common reasons for ICU admission of children after intoxication. Respiratory insufficiency may be neurologic or pulmonary in origin.

Impaired respiratory drive leading to hypoventilation or apnea may develop as a result of ingestion of CNS depressant drugs. Alternatively, other drugs may stimulate respiration by increasing central respiratory drive (e.g., salicylates, theophylline), inducing a respiratory alkalosis. Patients ingesting such drugs are at risk for eventual respiratory failure if excessive respiratory drive results in respiratory muscle exhaustion.

Central nervous system depressants also may impair the function of pharyngeal and hypopharyngeal musculature, resulting in obstruction of the upper airway by the tongue or other pharyngeal structures. A number of devices including nasopharyngeal or oropharyngeal airways may be sufficient to alleviate obstruction in these patients. Upper airway obstruction also may occur after exposure to agents (e.g., organophosphates, carbamates, scorpion envenomation) that increase pharyngeal and tracheobronchial secretions, obstructing either the hypopharynx, the glottic apparatus, or the tracheobronchial tree with secretions. Caustic agents and thermal injuries to the airway may cause airway obstruction due to the development of airway edema. The pediatric airway, with the characteristic narrowing that occurs in the subglottic region, is at great risk for obstruction from airway edema or increased airway secretions.

Respiratory failure also may occur owing to a wide variety of problems involving the lower

respiratory tract. Airway obstruction may occur secondary to increased tracheobronchial secretions or the development of bronchospasm due to the effects of airway irritants on bronchial smooth muscle. Aspiration of asphyxiant gases (e.g., volatile hydrocarbons, carbon dioxide) may interfere with oxygenation, with resulting CNS and organ system hypoxia.

Aspiration, inhalation, parenteral injection, or ingestion of a broad range of intoxicants may be responsible for parenchymal lung injury. A variety of trigger events, including hydrocarbon aspiration, inhalation of smoke or toxic gases, drowning, and a broad range of nonpulmonary triggers such as narcotic overdose, have been associated with the development of noncardiogenic pulmonary edema. Loss of integrity of the alveolar capillary permeability barrier allows leakage of proteinaceous fluid from alveolar capillaries into the alveolar airspaces, leading to the clinical manifestations of acute respiratory distress syndrome (ARDS): hypoxemia, radiographic opacities, decreased lung compliance and functional residual capacity, and increased dead space. The risk factors for the development of ARDS are similar to those in adults. Key elements in the criteria for the diagnosis of PARDS are summarized in Fig. 1.

Approximately 10% of children admitted to the PICU for poisoning may require endotracheal intubation [4]. Criteria for endotracheal intubation are found in Table 3.

Provision of sedation and analgesia and the use of a neuromuscular blocking agent to allow complete muscle relaxation before intubation are desirable in most patients to minimize the risk of traumatic intubation. The use of neuromuscular blocking agents, which by necessity result in apnea and complete loss of airway protective reflexes, requires that the airway manager have excellent airway skills to ensure that prompt intubation occurs without complications. Table 4 lists drugs commonly used for endotracheal intubation in children. Succinylcholine is now rarely used in children. Although it is listed here for reference, the routine use of atropine in pediatric intubation is not recommended but it can be considered in patients where there is bradycardia or increased risk of its development. Also, the new Pediatric

Age	Exclude patients with peri-natal related lung disease			
Timing	Within 7 days of known clinical insult			
Origin of Edema	Respiratory failure not fully explained by cardiac failure or fluid overload			
Chest Imaging	Chest imaging findings of new infiltrate(s) consistent with acute pulmonary parenchymal disease			
Oxygenation	Non Invasive mechanical ventilation	Invasive mechanical ventilation		
	PARDS (No severity stratification)	Mild	Moderate	Severe
	Full face-mask bi-level ventilation or CPAP ≥ 5 cm H ₂ O PF ratio ≤ 300 SF ratio ≤ 264	$4 \leq \text{OI} < 8$ $5 \leq \text{OSI} < 7.5$	$8 \leq \text{OI} < 16$ $7.5 \leq \text{OSI} < 12.3$	$\text{OI} \geq 16$ $\text{OSI} \geq 12.3$
Special Populations				
Cyanotic Heart Disease	Standard Criteria above for age, timing, origin of edema and chest imaging with an acute deterioration in oxygenation not explained by underlying cardiac disease.			
Chronic Lung Disease	Standard Criteria above for age, timing, and origin of edema with chest imaging consistent with new infiltrate and acute deterioration in oxygenation from baseline which meet oxygenation criteria above.			
Left Ventricular dysfunction	Standard Criteria for age, timing and origin of edema with chest imaging changes consistent with new infiltrate and acute deterioration in oxygenation which meet criteria above not explained by left ventricular dysfunction.			

Fig. 1 Pediatric acute respiratory distress syndrome (PARDS) definition. Use Pa_{O_2} -based metric when available. If Pa_{O_2} is not available, wean F_{IO_2} to maintain $\text{Sp}_{\text{O}_2} \leq 97\%$ to calculate oxygen saturation index (OSI; $[\text{F}_{\text{IO}_2} \text{ A} \sim \text{mean airway pressure A} \sim 100]/\text{Sp}_{\text{O}_2}$) or $\text{Sp}_{\text{O}_2}:\text{F}_{\text{IO}_2}$ (SF) ratio. For nonintubated patients treated with supplemental oxygen or nasal modes of noninvasive ventilation,

see Figure 2 for “at-risk” criteria. Acute respiratory distress syndrome severity groups stratified by oxygenation index (OI; $[\text{F}_{\text{IO}_2} \text{ A} \sim \text{mean airway pressure A} \sim 100]/\text{Pa}_{\text{O}_2}$) or OSI should not be applied to children with chronic lung disease who normally receive invasive mechanical ventilation or children with cyanotic congenital heart disease. CPAP = continuous positive airway pressure, PF = $\text{Pa}_{\text{O}_2}:\text{F}_{\text{IO}_2}$.

Table 4 Pharmacologic agents for endotracheal intubation

Drug	Dose	Duration of effect
Sedation/Anesthesia		
Midazolam	0.1–0.2 mg/kg	45–90 min
Ketamine	0.5–2 mg/kg	15–30 min
Fentanyl	2–5 $\mu\text{g}/\text{kg}$	30–60 min
Neuromuscular blockers		
Rocuronium	0.5–1 mg/kg	15–30 min
Vecuronium	0.1–0.2 mg/kg	30–60 min
Anticholinergic		
Atropine	0.02 mg/kg	2–3 h

Advanced Life Support guidelines no longer recommend a minimum dose for atropine [22].

A broad range of equipment is necessary to allow for the wide range of patient size. A selection of both straight and curved blades should be available. Capnography should be available to assist in confirming endotracheal tube placement

in the airway. The recommended endotracheal tube sizes based on average childhood size appear in Table 5. A rough rule of thumb for endotracheal tube size is $(\text{age in years} + 16)/4$ and the insertion depth is three times the endotracheal tube (ETT) size (e.g., a 4 mm ETT would be inserted to a depth of 12 cm). Proper placement should always be verified by radiography. A cuffed endotracheal tube is appropriate for all but the smallest patients and can help to facilitate effective mechanical ventilation in patients with poor lung compliance.

Mechanical Ventilation

After endotracheal intubation, appropriate ventilatory assistance is required. The choice of ventilator, mode of ventilation, and assisted breathing rate depends on the age and size of the patient and the clinical circumstances. Patients in whom the

Table 5 Equipment for endotracheal intubation

Age	ETT size ^a	ETT insertion depth (CM) ^b
Newborn (>2 kg)	3.5	9–10
1–6 months	3.5	10–11
1 year	4.0	12–13

lungs are functionally normal and who are intubated for airway protection or the provision of hyperventilation are managed much differently than patients with hydrocarbon aspiration and evolving ARDS. Although detailed discussion of ventilator management is beyond the scope of this chapter, some general issues are discussed here.

The goal of mechanical ventilation is to provide sufficient exchange of oxygen and carbon dioxide to provide for the metabolic needs of a patient with a minimum of adverse effects. In patients intubated primarily for airway protection and in whom the lungs are essentially normal, minimal ventilatory assistance is required. Little resistance to air entry exists, and compliance is normal, allowing air to enter and escape from the lungs with minimal ventilator pressure. No barrier to gas exchange exists, and oxygen crosses the alveolar epithelial and pulmonary capillary membranes easily.

If interstitial edema and inflammation reduce pulmonary compliance and increase airway resistance, air exchange occurs with more difficulty. The increase in resistance to airflow and decreased compliance require greater pressure to force gases into the airway, and an increase in FiO_2 is required

to provide the gradient of oxygen concentration necessary to overcome the barrier to gas exchange provided by the proteinaceous debris in the alveolus. This increase in ventilator pressure and oxygen concentration results in further injury to the lung in the form of barotrauma and oxygen toxicity, respectively. In these patients the goal is to provide sufficient respiratory support to maintain vital functions while minimizing further injury to the lungs.

Conventional ventilatory support provides respirations that mimic normal tidal breathing, providing a physiologically appropriate number of breaths of appropriate size and duration for age. Modern ventilators are designed to synchronize respirations with the patient's own breathing efforts (synchronized intermittent mandatory ventilation) in an effort to minimize the discomfort that the patient experiences with assisted ventilation. The various modes of conventional ventilation can be distinguished according to the method by which individual breaths are limited. In pressure-cycled ventilation, the peak inspiratory pressure is preset, providing for inspiratory airflow up to a predetermined maximum, with the size of individual breaths determined by peak inspiratory pressure, the rate of airflow, inspiratory time, and airway resistance and chest compliance. The size of individual breaths varies with changes in resistance and compliance. In volume-cycled modes of ventilation, air fills the lungs to a preset tidal volume at a flow rate determined by the tidal volume and a preset total inspiratory time. The pressure required to provide any given breath depends on and varies with changes in airway resistance and chest compliance. In both forms of ventilation, the desired goal is the achievement of stable minute ventilation (the product of tidal volume and respiratory rate). As the severity of lung disease increases and as pulmonary compliance worsens, the peak inspiratory pressure required to provide a given tidal volume increases. Excessive ventilator pressures have been associated with the development of ventilator-associated lung injury or barotrauma. Maintaining peak inspiratory pressure at the minimum value necessary to provide adequate

ventilation and oxygenation is essential to successful ventilator management. As a rule of thumb, peak inspiratory pressure should be maintained below 35 cm H₂O whenever possible.

In patients with significant parenchymal lung disease, alveolar collapse and ventilation/perfusion mismatching result in failure of oxygenation of the blood, with resulting desaturation of arterial blood and tissue hypoxia. FiO₂ should be adjusted to maintain adequate PaO₂ and hemoglobin oxygen saturation. The use of high levels of supplemental oxygen (FiO₂ >0.5) is associated with the development of pulmonary oxygen toxicity. Maintenance of adequate lung volume, which minimizes ventilation/perfusion mismatching within the lung, minimizes the need for supplemental oxygen. Lung volume is maintained best by the addition of positive end-expiratory pressure in the ventilator circuit. The appropriate level of positive end-expiratory pressure is determined by the severity of lung disease and the degree to which ventilation/perfusion inequality exists within the lung. The optimal level of positive end-expiratory pressure must be individualized to the specific situation and it is the level of positive end-expiratory pressure that maintains alveolar patency without overdistention and that allows maintenance of FiO₂ at nontoxic levels (FiO₂ <0.6).

Ventilator-induced lung injury is recognized to be an important factor in the outcome of ARDS. Lung protective strategies that emphasize low pressure, low-tidal volume ventilation with tolerance of respiratory acidosis (pH >7.15), and hypoxia (oxygen saturations >88%) have been suggested in an effort to minimize iatrogenic lung injury [23]. This strategy is termed *permissive hypercapnia* [24, 25]. No randomized pediatric studies have been performed to assess the efficacy of these strategies in children with ARDS, although they are widely practiced.

For some patients with severe lung injury, despite lung protective strategies, the patient's requirement for ventilator support and supplemental oxygen may be great enough that conventional mechanical ventilation poses an unacceptable risk of ventilator-associated lung injury. For these patients, alternative strategies of

cardiorespiratory support must be considered. These strategies include high-frequency ventilation and ECMO. Published information regarding the use of alternatives to conventional ventilation in poisoned children is limited. The common pathophysiology of ARDS allows extrapolation of data from nontoxicologic causes of ARDS to the poisoned patient, however.

High-Frequency Ventilation

High-frequency ventilation is an alternative to conventional ventilation in which small volumes of air are injected into the airway at high frequencies. Two primary modes of high-frequency ventilation are currently in use. In high-frequency jet ventilation, jets of air are delivered into the airway via a high-velocity injector port at rates of 100–600 breaths/min. Inhalation in this mode of ventilation is active, whereas exhaled gases are expelled passively. Total lung inflation is controlled primarily by adjustment of tidal volume and inspiratory time. The precise mechanism of gas exchange in high-frequency jet ventilation is poorly understood. High-frequency oscillatory ventilation is a more commonly used form of high-frequency ventilation in children (3100A and 3100B high-frequency oscillatory ventilator, CareFusion, Yorba Linda, CA); a piston or diaphragm actively oscillates air into and out of the lung at high frequencies, generally ranging from 6 to 12 Hz. The mechanism of gas exchange in high-frequency oscillatory ventilation is similarly poorly understood. The purported advantage of high-frequency ventilation lies in the small tidal volumes (generally 1–3 mL/kg) used, which result in lower peak airway pressure and less ventilator-associated lung injury (Grade III evidence). In patients with significant alterations in compliance and in patients with significant air leak, high-frequency ventilation provides a theoretically less traumatic alternative to conventional ventilation. In patients with severe ARDS, early initiation of high-frequency ventilation has been shown to result in significant improvement in oxygenation with lower frequency of barotrauma [26].

Noninvasive Ventilation

Although the role of noninvasive ventilation in the pediatric poisoning patient is not established, there are a number of noninvasive modalities that are used in pediatrics to provide an alternative to endotracheal intubation and mechanical ventilation with its associated risks and complications.

A brief description of these devices and techniques will be provided here.

Heated, humidified high-flow nasal cannula (HHHFNC), providing heated and humidified gas at a high rate of flow (ranging from 3 to 50 l per minute), is utilized in patients ranging from premature neonates to adults. A blended oxygen/air mixture, humidified to 100% relative humidity and heated to body temperature, is blown into the airway through specially designed nasal cannulae at flow rates well in excess of the patient's minute ventilation. The mechanisms of action of HHHFNC remain incompletely defined. An evolving body of evidence suggests that the high-flow rates washout gases from the nasopharyngeal dead space, improve oxygen delivery and CO₂ clearance. Distention of pharyngeal tissues reduces resistance to airflow in the nasopharynx, thus decreasing work of breathing, and delivery of positive distending pressure to facilitate lung recruitment preventing atelectasis [27]. HHHFNC has been utilized in pediatric patients for prevention of apnea, facilitation of oxygen delivery for patients with hypoxia, reduced need for invasive mechanical ventilation, and transition from mechanical ventilation back to independent breathing. Few randomized trials of HHHFNC have been done in pediatric patients beyond the neonatal period, and no cases have documented its use in poisoned patients, but its increasing use for a broad range of indications in both children and adults makes its use in poisoned patients likely.

Continuous positive airway pressure, or CPAP, is a similar noninvasive mode of support in which a fixed distending pressure is applied to the pharyngeal airway. This modality is generally applied via nasal cannulae or nasal mask (nasal CPAP) or by full face mask (face mask CPAP). Positive

pressure is applied to the pharynx, with or without a device that retards expiratory flow. The positive pressure in the airway is transmitted to the lung, facilitating lung recruitment, decreasing atelectasis, and improving oxygenation. CPAP differs from HHHFNC in that a fixed pharyngeal pressure is targeted, with lower flow rates and less variability in airway pressure than HHHFNC. Both CPAP and HHHFNC reduce work of breathing and facilitate oxygenation by maintaining the airway in an open state. CPAP has been used after exposure to pulmonary irritants including hydrocarbon aspiration and chlorine inhalation.

Noninvasive ventilation, also known as bilevel positive airway pressure (BiPAP), is a form of respiratory support which provides mechanical ventilatory assistance via a nasal or full face mask. In this modality, the ventilator provides positive distending pressure between breaths (expiratory positive airway pressure or *ePAP*), along with a higher level of positive pressure with patient breaths (inspiratory positive airway pressure or *iPAP*), thereby augmenting the patient's respiratory work to facilitate tidal breathing. In addition to setting *ePAP* and *iPAP*, a minimum rate can be set to facilitate minute ventilation. This mode of ventilation is useful for patients requiring mechanical support of breathing in the treatment or prevention of respiratory muscle weakness or fatigue, for patients with parenchymal lung disease, and to facilitate transition to and from invasive mechanical ventilation. BiPAP provides mechanical support for patients with respiratory failure, without the attendant risks of endotracheal intubation (airway injury, infection, etc.) and with less discomfort, thereby requiring significantly less sedation. BiPAP does require that the patient have sufficient airway protective reflexes to avoid aspiration in the event of emesis and that the patient be sufficiently cooperative to keep a tight fitting mask in place. Noninvasive positive pressure ventilation can also be provided through a nonocclusive nasal cannula (RAM Cannula[®], Neotech) connected to a standard ventilator such as the Servo-i[®] (Maquet Medical Systems USA). Parameters specified are similar to BiPAP. The cannula provides 60–80%

occlusion of the nares. It is used in the PICU and neonatal intensive care unit to treat infants with respiratory distress from a number of causes and appears to be well tolerated.

The RTX ventilator (Hayek Medical) is a negative pressure ventilator that utilizes a cuirass on the thorax to provide biphasic ventilation. Cuirasses are available in sizes from infant to adult. Although there are no case reports of its use in intoxicated patients, it has been used in a number of different scenarios of respiratory failure [28, 29].

The role of noninvasive respiratory support in patients after poisoning is poorly defined. A number of case reports have documented the use of noninvasive respiratory support for patients with exposure to intoxicants. Noninvasive ventilation has been used in overdose situations involving opioids and other respiratory depressants [30], for support of lung-injured patients [31], and for treatment of pulmonary edema following amlodipine overdose [32].

Mechanical Circulatory Support/ECMO

For children with massive overdoses of drugs with cardiac depressant, proarrhythmic, or vasodilator effects who are unresponsive to the therapies described above, mechanical support of the circulation may be the only alternative to mortality.

The most commonly available, most invasive, and probably most effective mechanical supportive device is ECMO. In ECMO, the patient's blood is removed from the body; pumped through a membrane oxygenator, which adds oxygen and removes carbon dioxide from the blood; and then returned to the body. Extracorporeal membrane oxygenation is a treatment with substantial risk, because it requires systemic anticoagulation and is technically sophisticated, requiring the expertise of a center familiar with and prepared to perform ECMO regularly. Complications of ECMO, even in centers that perform ECMO regularly, include life-threatening hemorrhage, embolic complications including cerebrovascular accidents, development of multisystem organ

failure, and risk of systemic infection. ECMO is indicated only in situations in which the risk of mortality is great and only in centers with established experience (Grade III recommendation).

Extracorporeal membrane oxygenation is only indicated in cases of reversible cardiorespiratory failure. As such, poisoning represents an ideal indication provided it can be instituted in a timely fashion. Many tertiary pediatric centers offer rapid response ECMO teams and can have patients cannulated and on ECMO in about 30 min [33]. Two forms of ECMO are available. Venoarterial ECMO, in which cannulae are placed via a central vein (usually jugular vein) and central artery (usually carotid artery), provides complete cardiorespiratory replacement for the duration of time necessary for clearance of an intoxicant and recovery of cardiac and respiratory function. Blood is removed from the right atrium and returned to the arterial circulation into the aortic arch.

Venovenous ECMO, in which either two venous cannulae (usually femoral vein and jugular vein) or one double-lumen venous cannula is placed, primarily provides replacement of respiratory function and requires adequate native cardiac output for adequate tissue perfusion. Venoarterial ECMO is most useful if the primary problem is myocardial dysfunction and poor cardiac output or combined cardiorespiratory failure; venovenous ECMO may be considered if the primary problem is pulmonary, as in hydrocarbon aspiration or smoke inhalation associated with carbon monoxide poisoning. The advantage of venovenous ECMO in this circumstance is the avoidance of return flow into the arterial circulation, hence decreasing the risk of systemic thromboembolic complications, such as cerebrovascular accidents and peripheral arterial embolism. ECMO has been used in selected circumstances with ready availability of this specialized technology in a timely fashion during the acute deterioration of a patient after a lethal ingestion. The use of ECMO has been reported in patients with overdoses with a variety of intoxicants causing intractable cardiovascular or respiratory collapse [34]. In one review, the mean time on ECMO was 35 h, and the survival rate was 80% [35].

Circulatory Assist Devices

The intraaortic balloon pump (IABP) and ventricular assist device (VAD) are widely used as cardiovascular assistive devices in adults with intractable cardiac failure, in most cases after cardiac surgery, after myocardial infarction, or as a bridge to transplant in patients with congestive cardiomyopathy. The size of the patient may limit the use of an IABP in children. A VAD is more suited to the nonemergent setting of more chronic ventricular failure. A pediatric center that has access to these modalities is highly likely to have an ECMO program, and ECMO can be instituted in a timelier fashion although a VAD might still find use in drug-induced chronic ventricular dysfunction such as that caused by anthracyclines as a bridge to recovery or transplantation.

Renal Toxicity

The indications for hemodialysis in the poisoned child include both extracorporeal drug removal and renal replacement therapy for patients with drug or toxin-induced renal dysfunction. Indications for extracorporeal removal are further discussed elsewhere in the book and are similar to the criteria used in adults. Drugs and toxins that might be associated with acute renal dysfunction in the pediatric patient are listed in Table 6. Hemodialysis can be performed in patients under 3 kg, so patient size is rarely a barrier to its use although, depending on the size of the patient and hemodynamic status, it might be necessary to prime the circuit with blood instead of the usual solutions.

Organ Donation

Despite the best efforts of the care team, it is not possible to save every child with an intoxication. Particularly in cases where there was significant hypoxic-ischemic central nervous system injury, patients may progress to brain death. Although the criteria for the diagnosis of brain death in children

Mercuric salts

can vary by jurisdiction, national guidelines have been published and adopted widely [36]. The first brain death examination must be performed *at least* 24 h following the brain insult. Since severe drug-induced central nervous system depression can mimic brain death, it is important to allow adequate time, individualized to the pharmacology of the intoxicating substance, for the offending agent(s) to fall to levels that are not clinically important before proceeding. Two brain death examinations, each performed by two physicians independently, must occur before making the declaration of brain death. These two examinations should be separated by at least 24 h in infants under 1 month of age and by at least 12 h in older infants and children. Intoxication itself is not a contraindication to organ donation, although medicolegal considerations necessitate close communication and coordination between organ retrieval agencies, medical examiners, and law enforcement.

Exposures to toxicants in the workplace can cause severe illness and death similar to intentional poisonings and overdoses. In some cases, without a careful occupational history, the relationship between the job and the illness may be missed. Prolonged exposure to an insoluble gas, such as nitrogen dioxide after arc welding in a confined space, can cause a delayed pulmonary injury and acute respiratory distress syndrome (ARDS) that occurs one day later, when the link may go unnoticed. Careful questioning about the particular sequence of events is important when an illness occurs after performance of a common task. Another example is exposure to phosgene gas after torch-cutting or welding metal that had been recently degreased with a chlorinated hydrocarbon solvent. Alternatively, a worker may experience a delayed illness such as metal fume fever (MFF) if he or she is welding on galvanized metal or had been working in close proximity to someone doing so. It is important to ask not only about the job of the ill worker but also about the nature of the workplace and the other processes being performed there.

The U.S. Department of Labor, Bureau of Labor Statistics, reported that there were 4,679 occupational fatalities in 2014, most caused by physical hazards, accidents, and falls. Of these

fatalities, 390 (8.3%) were due to exposure to harmful substances or environments, and 137 (2.9%) were due to fires and explosions [1]. Of the 1,162,210 nonfatal occupational illnesses and injuries involving lost work days in 2013, 4.8% were due to exposures to harmful substances [2]. Globally, ILO and WHO data indicate that work-related diseases account for 2,022,000 deaths annually, 32% due to work-related cancer, 23% due to work-related cardiovascular diseases, and 17% due to communicable diseases [3]. The actual incidence may be higher because the connection between work and the illness may be missed unless a detailed occupational history is obtained.

It is imperative that every poisoned worker be considered an index case in order to prevent further cases from that workplace or from those working with that same chemical or process. The clinician must ascertain whether other workers from the index patient's work environment have been similarly exposed and therefore may also be at risk. Many countries have reporting requirements that mandate the clinician who becomes aware of workplace injuries notify relevant governmental agencies.

Commensurate with the orientation of this book, this chapter highlights the most important occupational exposures that may result in critical illness or death. A comprehensive review of all exposures is beyond the scope of this book. This chapter stresses the workplace-related issues regarding these exposures. Since accidental ingestion of a toxicant is exceedingly rare in the workplace, airborne exposures and subsequent inhalation by the worker is the predominant exposure pathway for nearly all occupational illnesses and injuries of consequence. Some chemicals also have a "skin designation," meaning systemic effects and/or toxicity can occur due to transcutaneous absorption. More comprehensive discussions of the particular toxicants discussed here may be found in their respective chapters. Minor illnesses, such as occupational dermatoses, and chronic diseases, such as asbestosis, beryllium disease, cancers, and the pneumoconioses, are not addressed in this chapter.

Occupational Pulmonary Toxicology

Occupational Asthma

Asthma is a common chronic condition, affecting about 7.7% of the working population, and occupational disease surveillance data indicate that occupational asthma is the most common occupational respiratory disease in industrialized nations [4]. Occupational asthma is second only to contact dermatitis as the most common work-related disease. The all-encompassing term work-related asthma (WRA), includes asthma that may be *caused by* the workplace exposure, which is termed Occupational Asthma or OA, or preexisting asthma that may be *aggravated by* workplace exposures (termed Work-Exacerbated Asthma or WEA). Using this extremely broad definition, it has been estimated that 3–33% of all asthma cases may be considered WRA [5–7]. The American Thoracic Society estimated in 2003 that 15% of new onset asthma in adults is due to work [8], and that 25% of adult asthmatics have either OA or WEA [4, 7].

WRA is diagnosed when there is a work-related variable airway obstruction or airway hyperresponsiveness resulting from exposures encountered in the workplace. Occupational asthma can be further subcategorized as sensitizer-induced asthma (SIA) and irritant-induced asthma (IIA-also known as *reactive airways dysfunction syndrome* or *RADS*). SIA is far more common and is the more classic form of occupational asthma which requires a variable amount of time between the first exposure and onset of illness, whereby the worker becomes sensitized to the offending agent. Once the worker is sensitized, exposure to even minute quantities of the agent may cause significant signs and symptoms. Most SIA is caused by exposure to high-molecular-weight organic compounds that are considered "complete allergens," such as animal dander and plant proteins. The asthma is a manifestation of type I or IgE-mediated immediate-type hypersensitivity reactions. Low-molecular-weight (LMW) compounds can cause SIA by acting as incomplete allergens or haptens (e.g.,

antibiotics, metals) or by other mechanisms that are poorly understood (toluene diisocyanates [TDI], trimellitic anhydride [TMA] are but two examples). The chemical structure of the LMW agent is an important factor: the presence of at least two reactive groups with the ability to form bonds with native human macromolecules, such as albumin, seems to be required for such an agent to cause SIA [5, 7]. More than 200 LMW compounds have been implicated in the cause of occupational asthma, the most well known being plicatic acid in western red cedar, TDI, and colophony (rosin) [5, 7].

Exposure to an overwhelming dose of an irritating gas, dust, mist, fume, or fire smoke can cause reactive airways dysfunction syndrome (RADS), a form of OA which develops without an intervening latent period. True RADS occurs only after an acute, intense, high level exposure, often in a confined space where the victim cannot escape the exposure. This irritant-induced asthma is a form of occupational asthma that is usually short-lived, since most RADS victims improve within a year; rarely, generalized airway hyperresponsiveness to temperatures, dusts, or irritants can persist in patients with RADS (see irritant gas exposure discussion below) [25, 27].

The physician evaluating a patient who presents with bronchoconstriction always must consider the possibility of work-related asthma, especially in a patient with no prior history of asthma, with asthma of recent onset, or with acute exacerbations of stable asthma. Careful questioning regarding the time of onset of symptoms as they relate to exposures at work can be helpful.

SIA can have a biphasic or dual response, in which exposure to the allergen may induce an immediate bronchoconstriction, known as the *early response*, and a delayed or *late response* approximately 4–8 h later. The early response often is self-limited, only to be followed later by the inflammation, airway hyperresponsiveness, and airway obstruction seen in the late response. Some workers may exhibit only the late response, becoming ill hours after leaving the workplace, when the causal relationship may not be apparent.

The presence of the dual response may hinge on factors such as the type of compound, dose, length of exposure time, and concomitant use of medication. LMW agents seem more likely to induce an isolated late response, whereas high-molecular-weight “complete” allergens more commonly cause a dual response [5, 7].

Treatment of occupational asthma acutely is no different than conventional asthma treatment and consists of inhaled β -agonists, supplemental oxygen, and systemic corticosteroids as the condition dictates. As mentioned above, a particularly sensitive individual with SIA may react after an exposure to even minute amounts of the offending allergen and could potentially be in status asthmaticus. Severe exacerbations associated with hypoxia or carbon dioxide retention or both require treatment in the intensive care unit. Long-term management hinges on identifying the sensitizer when possible and removing the patient from further exposure. Tables 1 and 2 list exposures and occupations known to be associated with sensitizer-induced occupational asthma. Patients presenting after an exposure to an irritant gas, while at risk for RADS, may also present initially with acute respiratory distress syndrome (ARDS- see below). Rarely, high dose exposures to irritant gases can cause permanent RADS, and victims may have significant long-term sequelae that do not improve with removal from the workplace.

Toxic Inhalant Injury

Many occupations have potential exposure to gases, and often these have significant potential for lung injury or systemic toxicity. Because oral ingestion of toxins in the workplace is uncommon, the primary routes of systemic entry are pulmonary, and, to a lesser extent, dermal. Gases of toxicologic importance can be divided into three major categories: (1) simple asphyxiants, (2) toxic or chemical asphyxiants, and (3) irritant gases. Simple asphyxiants have no inherent toxicity other than displacing oxygen in inspired air, thus inducing anoxia. This toxicity is especially important in

Table 1 High-molecular-weight sensitizing agents and jobs associated with occupational asthma

HMW sensitizing agents	Associated occupations/industries
Animal dander	Animal handlers, veterinary workers, farmers
Pigeons (e.g., excreta, feathers)	Pigeon breeders
Chickens, turkeys	Poultry processing workers
Mice	Laboratory technicians
Guinea pigs	Laboratory technicians
Insects (bees, beetles, weevils, mites, silkworms, flies, others)	Many outdoor workers, silkworm farmers, insect research workers, granary workers, others
Grains (wheat, rye, buckwheat)	Farmers, grain mill workers, silo workers
Raw tobacco	Tobacco industry workers
Flours (wheat, rye)	Bakers, food processing workers
Enzymes	
<i>Bacillus subtilis</i>	Detergent manufacturers
Papain	Meat processing workers
Trypsin, pepsin	Pharmaceuticals workers
Wool	Wool workers, sorters
Marine organisms (prawns, crabs, oysters)	Prawn workers, oyster processing workers, crab processing workers
Foods (spices, grains, flours)	Chefs, food industry workers, food preparers
Natural rubber latex	Health care workers, rubber industry workers
Gums (acacia, arabic, tragacanth, karaya)	Pharmaceuticals workers, printers
Coffee beans, tea leaves	Coffee production workers, tea workers
Castor beans	Castor oil production workers
Seeds (flaxseed, cottonseed, linseed, psyllium seed)	Bakers, oil extraction workers, seed workers
Woods (oak, mahogany, California redwood, others)	Sawmill workers, carpenters, woodworkers
Hops	Brewery workers, farmers
Fungi, molds	Farmers, bakers, various industrial workers

Data from Refs. [4, 5, 7–11]

HMW high molecular weight

confined spaces, where the lack of air movement and ventilation may allow these gases to replace oxygen in the ambient air. Some simple asphyxiant gases like carbon dioxide are heavier than air and tend to accumulate in low areas, so workers at lower levels are at increased risk. Similarly, a victim who collapses to the floor due to injury or asphyxiation is subjected to higher concentrations of these heavier gases. In the chemical production worker, confined spaces such as reactor vessels may contain no oxygen; entry for vessel cleaning requires self-contained breathing apparatus or other supplied air respirators, and specific lock-out, tag-out procedures and specific training to prevent worker exposures.

Simple Asphyxiants

The simple asphyxiants commonly encountered by chemical workers include nitrogen, methane, ethane, ethylene, propylene, carbon dioxide, butadiene, isobutylene, and hydrogen. When encountered in confined spaces, simple asphyxiants can cause anoxic central nervous system (CNS) injury due to oxygen deprivation. The degree of injury depends on the extent and duration of anoxia. Additionally, some simple asphyxiants such as the hydrocarbons mentioned above pose a significant fire or explosive hazard. These confined-space exposures usually occur in the situation with inexperienced workers, inadequate safety training,

Table 2 Selected low-molecular-weight sensitizing agents and jobs associated with occupational asthma

LMW sensitizing agents	Associated occupations/industries
Antibiotics (penicillins, cephalosporins, tetracyclines)	Pharmaceuticals workers
Drugs (α -methyldopa, cimetidine, hydralazine, opiates, penicillamine, others)	Pharmaceuticals workers
Inorganic chemicals	
Ammonium persulfate	Beauticians, chemical production workers
Fluoride	Aluminum pot-room workers
Metals	
Aluminum	Aluminum smelting workers
Chromium salts	Leather tanning workers, metal plating workers, hard metal workers
Cobalt	Tungsten carbide hard metal workers
Nickel	Metal plating workers
Palladium	Metal plating workers, jewelers
Platinum	Platinum refining workers, electroplating workers, fluorescent screen manufacturers, jewelers
Vanadium	Ferrovanadium workers (hard metal workers)
Zinc	Metal plating workers
Organic chemicals	
Abietic acid (colophony-pine resin)	Soldering workers, electronics manufacturers
Acrylates	Glue workers
Aldehydes (formaldehyde, glutaraldehyde)	Hospital workers, laboratory technicians
Amines (ethanolamine)	Soldering workers, paint application workers, machining metal workers
Anhydrides (trimellitic anhydride, phthalic anhydride)	Plastics workers, epoxy resins workers
Dyes	Dye industry workers, fabrics workers
Insecticides (pyrethrins, organophosphates)	Farmers, insecticide applicators
Isocyanates	
Toluene diisocyanate	Polyurethane foam manufacturers
Diphenylmethane	Foundry workers, paint application workers
Plicatic acid (western red cedar)	Lumber workers, loggers, carpenters, cabinet-makers
Paraphenylenediamine	Fur dyers, chemical workers
Phenol	Chemical workers, laboratory workers
Piperazine	Chemical processing workers
Styrene	Chemical production workers, polymer industry workers

Data from Refs. [4, 5, 7–11]

or lack of proper supervision. Treatment of simple asphyxiant exposure involves removing the victim from the source, ensuring adequate ventilation, and providing supplemental oxygen.

Chemical Asphyxiants

The gases considered chemical asphyxiants act either by decreasing the oxygen-carrying capacity of the blood (carbon monoxide [CO]) or by interfering with cellular utilization of oxygen (cyanide,

hydrogen sulfide, and CO). These toxins are covered in detail in their respective chapters in this book.

Irritant Gases

Irritant gases cause injury patterns directly related to their water solubility (Table 3). Highly soluble gases, such as hydrogen chloride (HCl), ammonia, sulfur dioxide, formaldehyde, and acid vapors, cause immediate irritation of the mucous membranes of the upper respiratory tract because they dissolve easily in the moisture of these tissues. These soluble gases first are deposited in the upper airways, which acts as a “scrubber,” lowering the concentration in the lower respiratory

tract. After significant exposure to highly soluble gases, the symptoms of burning in the eyes, nose, mouth, throat, and trachea tend to limit the exposure duration because the victim will not tolerate the irritation and will rapidly exit the area, if possible. The lack of these upper respiratory signs or symptoms after a known exposure to a highly soluble gas virtually rules out any significant exposure to that soluble gas and obviates the need for prolonged observation. By contrast, workers with significant symptoms of upper respiratory tract burning and irritation associated with signs of mucosal and conjunctival inflammation, laryngeal symptoms, and cough indicate a significant dose of the water-soluble gas was inhaled

Table 3 Relative solubility of common irritant vapors and gases

Gas	Conversion factor	MW (d)	Relative vapor density (Air = 1)	Solubility in water	Relative solubility
Hydrofluoric acid (HF)	1 ppm = 0.82 mg/m ³	20.006	1.86	Freely soluble in water	Very high
Hydrochloric acid (HCl)	1 ppm = 1.49 mg/m ³	36.46	1.27	82.3 g/100 mL water	Very high
Chloramine (NH ₂ Cl): formed from bleach + NH ₃		51.48	NA (liquid)	Freely soluble in water	Very high
Formaldehyde (CH ₂ O)	1 ppm = 1.23 mg/m ³	30.03	1.04	55 g/100 mL water	High
Ammonia (NH ₃)	1 ppm = 0.70 mg/m ³	17.03	0.59	47 g/100 mL water	High
Fluorine (F ₂)	1 ppm = 1.55 mg/m ³	38	1.31	Reactive	Medium high
Acrolein (C = C = O)	1 ppm = 2.29 mg/m ³	56.1	1.9	21 g/100 mL water	Medium high
Sulfur dioxide (SO ₂)	1 ppm = 2.62 mg/m ³	64.065	2.263	17.7 g/100 mL water	Medium high
Methyl isocyanate (MIC) (CH ₃ NCO)	1 ppm = 2.34 mg/m ³	57.06	1.42	10 g/100 mL water	Medium high
Chlorine (Cl ₂)	1 ppm = 2.90 mg/m ³	70.9	2.47	1.46 g/100 mL water	Medium
Phosgene (carbonyl chloride [COCl ₂])	1 ppm = 4.05 mg/m ³	98.9	3.48	0.9 g/100 mL water	Low
Chlorine dioxide (ClO ₂)	1 ppm = 2.76 mg/m ³	67.46	2.33	0.3 g/100 mL water	Low
Nitrogen dioxide (NO ₂)	1 ppm = 1.88 mg/m ³	46	2.62	0.3 g/100 mL water	Low
Ozone (O ₃)	1 ppm = 1.96 mg/m ³	48	1.66	0.001 g/100 mL water	Very low

Data from Refs. [12–15]

MW molecular weight, NA not applicable

and raises the possibility of lower respiratory tract injury. Under these circumstances admission and observation is indicated (level III recommendation). Significant exposures to highly soluble gases can cause ARDS hours later. Immediate and long-term sequelae may include RADS (see full discussion below), or other obstructive defects including BOF, bronchiectasis, and bronchial stenosis [16, 17].

Phosgene, oxides of nitrogen, and ozone are poorly water-soluble gases. These are discussed in greater detail in ► Chap. 100, “Irritant and Toxic Pulmonary Injuries.” These insoluble gases cause little or no upper respiratory tract symptoms. Because there is no initial irritation, employees often are unaware of ongoing exposure, and much longer exposure durations are tolerated. The longer exposures allow a higher concentration to reach the lower airways, along with the lack of deposition in the moisture of the upper airway mucosa as happens with soluble gases. Delayed alveolar injury is possible after insoluble gas exposures, and the onset of lower respiratory tract injury and ARDS occurs later, often several hours or a day after a significant exposure. Phosgene is encountered in chemical synthesis as an intermediate for isocyanate and pesticides or as a byproduct when chlorinated hydrocarbons are burned or heated. Phosgene was a World War I warfare agent responsible for numerous deaths. Heavier than air, it accumulates in lower areas, making it an ideal agent for the trench warfare that was common during World War I. The only clue to phosgene exposure may be the reported odor of freshly mown hay.

Oxides of nitrogen (NO , NO_2) are commonly found in recently stored silage (silo filler’s disease), from combustion products (especially of nitrocellulose films [18]), from oxidation of ambient nitrogen during high-temperature arc welding, or from gas-powered Zamboni ice resurfacers in indoor ice rinks [19, 20].

Because of the lack of upper respiratory tract irritation from the low solubility gases, patients often go home and develop these symptoms remote from the worksite. The clinical picture may present as ARDS, and sepsis or CHF or

some other nonoccupational etiology may be suspected if an adequate occupational history is not obtained. Treatment consists of supplemental oxygen and ventilatory support as dictated by the clinical picture. A full discussion of potential therapeutic approaches can be found in ► Chap. 16, “Treatment of Acute Respiratory Distress Syndrome in the Poisoned Patient.” Depending on the severity of injury, mortality rates from severe ARDS may be significant, and rarely patients who recover may be left with permanent pulmonary impairment. Based on very old evidence, corticosteroids maybe useful to prevent the late sequelae of bronchiolitis obliterans fibrosa that is seen after nitrogen dioxide exposures [21, 22] (Level III recommendation). Their value in other toxic inhalational injuries is suggested by animal studies but is not verified in humans [16].

Medium-solubility gases, such as chlorine (Cl_2), have dissolution rates in the upper airway moisture that are midway between highly soluble and poorly soluble irritant gases. Significant medium-solubility gas exposures can cause upper airway symptoms of burning and irritation, but these may be milder than the highly soluble gases and may progress to lower airway injury and delayed pulmonary edema. Clinical suspicion and careful evaluation are necessary when making disposition decisions after exposures to medium-solubility gases. Chlorine behaves more like a highly water soluble gas, even though its rank in water solubility chart would suggest otherwise, since the chlorine dissolution equation: $\text{Cl}_2 + \text{H}_2\text{O} \Rightarrow \text{HOCl} + \text{HCl}$ is preferentially driven to the right due to the high water solubility of the hypochlorite (HOCl) and HCl produced, and may explain some of the prolonged signs and symptoms, as new HCl is continually formed as more Cl_2 dissolves [23, 24].

Reactive Airways Dysfunction Syndrome

RADS is an acute pulmonary injury that can occur after high-level exposure to an irritant gas. RADS is defined as a sudden onset of “acute irritant-induced asthma” that follows a single high-level, overwhelming exposure to an

irritant gas, vapor, or a similar overwhelming exposure to products of combustion in a fire (e.g., severe smoke inhalation injury) [25]. It has not been described after low-level, non-irritating exposures, or to brief exposures to soluble irritant gases or smoke.

The original criteria described by Brooks [25] were:

1. A documented absence of preceding respiratory complaints.
2. The onset of symptoms occurred after a single specific exposure incident or accident.
3. The exposure was to a gas, smoke, fume, or vapor which was present in very high concentrations and had irritant qualities to its nature.
4. The onset of symptoms occurred within 24 h after the exposure and persisted for at least 3 months.
5. Victims required immediate medical assistance and ICU admission.
6. Symptoms simulated asthma with cough, wheezing, and dyspnea predominating.
7. Pulmonary function tests (PFTs) may show airflow obstruction.
8. Methacholine challenge testing was positive.
9. Other types of pulmonary diseases were ruled out.

The development of RADS after an irritant exposure is actually a very rare event. RADS cases originally described by Brooks and subsequent reports in the medical literature are characterized by intense high-level exposures to a pulmonary irritant which results in acute respiratory symptoms of a severity requiring immediate medical attention and hospitalization, usually in an intensive care unit. Often, the exposure occurs in a confined space, an environment with limited ventilation, or in circumstances in which the individual was not able to immediately escape the exposure due to an injury.

It is very likely that RADS is frequently misdiagnosed. Shakeri et al. (2008) conducted a systematic review to identify those agents reported as being associated with reactive airways dysfunction syndrome (RADS) from 1985 to

2005. They used the Brooks criteria above to evaluate how many of these reported RADS cases actually met the criteria for that diagnosis. The authors found that in >40% of cases, the physical exam and diagnostic findings and exposure scenario did not support a diagnosis of RADS, despite being reported as such. In many cases, data was missing; the purported causative agents weren't even identified in some cases. The most commonly reported agent was chlorine, followed by TDI and oxides of nitrogen. The authors did note that a reporting bias occurs, such that once an agent has been reported to cause RADS in the appropriate setting, submitting a new RADS case report of that agent would have a small chance of being published. This would tend to show a bias for only unusual or new agents being accepted for publication [26].

The massive irritant exposures that cause RADS produce damage to bronchoepithelial cells lining the airways, and this can lead to persistent airway inflammation by way of release of inflammatory mediators and subsequent sensitization causing nonspecific heightened airway responsiveness. These effects do not occur after trivial exposures. True RADS victims always have need for immediate intensive care admission because of the severity of the airway injury.

It is not possible to exactly quantify the magnitude of the irritant exposure that will cause RADS, but almost all cases of RADS are associated with an unanticipated massive accidental release of irritant gasses, either due to an explosion or from a sudden release under pressure. This also usually occurs in an enclosed environment or from smoke inhalation in victims caught in structural fires. Patients so affected by RADS report asthma-like complaints acutely (immediately after soluble irritant gas exposures, and within 24 h in the case of insoluble irritant gasses) after a huge exposure. This irritant-induced asthma does not require any latency or immunologic sensitization that is so characteristic of the more common sensitizer-induced occupational asthma (see SIA above) [25, 27, 28].

The exact incidence of RADS is not known, but due to the extreme exposure levels that are

required to cause it (i.e., an overwhelming gas exposure that induces respiratory distress requiring hospitalization), the syndrome is very uncommon, and in this author's experience, often misdiagnosed. It has been reported that RADS accounts for only a small fraction (<20%) of workers with "occupational asthma." There is no "chronic irritant-induced RADS," since people alleging this condition are, in reality, suffering from an exacerbation of a pre-existing asthmatic condition (and therefore have WEA), a mild or relatively asymptomatic asthma patient who had not previously required medications, or persons with pre-existing baseline airway hyperresponsiveness (which has quite a significant prevalence in the normal population). This can also be true for a previously undiagnosed COPD patient whose disease progressed to become symptomatic. When tested, true RADS patients respond with a "positive" methacholine challenge test with a PC20 of 8 mg/mL (the concentration which causes a 20% or more reduction in FEV1), and there are typically no radiographic abnormalities after the acute inciting incident has resolved [27]. It also must be understood that there are a certain number of asymptomatic individuals who do not have RADS but have a positive methacholine challenge test, since there is a baseline positive reactive airway incidence in the normal population- 10–40% in nonasthmatic normal population, depending on the study – to as high as 50% or more in other nonasthmatic medical conditions [29, 30].

By definition, then, true RADS cases present critically ill, with dyspnea, hypoxia, and acute lung injury. They may also have stridor as a manifestation of concomitant upper airway injury. Chest radiographs often can progress fairly rapidly to reflect ARDS. Treatment consists of securing the airway and providing oxygenation and ventilatory support, with PEEP as needed, along with intensive supportive care. Systemic corticosteroids have been used, especially when significant reactive airway symptoms are present, and presumably to prevent sequelae. However, no controlled human clinical trials have proven the efficacy of corticosteroids in this situation, although there is evidence for efficacy in animal

models [31] (level of evidence II-3). Antibiotics are probably contraindicated due to selecting out resistant organisms, unless radiographic, microbiologic, and clinical confirmation of infection/pneumonia is present. In the case of chlorine gas and other acid vapor exposures, nebulized standard sodium bicarbonate (NaHCO_3) for injection (diluted with 1:1 with normal saline) is advocated and has been anecdotally reported several times to provide symptomatic relief of upper airway burning symptoms [32–34]. In Turkey, where bleach-acid cleaning mixtures are used frequently and have been reported as having caused RADS, a randomized, placebo-controlled clinical trial showed benefits of NaHCO_3 nebulizers in improving FEV1 measurements and subjective improved symptoms in the immediate postexposure period (patients in both arms also received nebulized albuterol and intravenous corticosteroids). No long-term follow-up was performed [35] (Level of evidence I). In hydrogen fluoride (HF) exposure, dilute calcium gluconate solution (3:1 NS to calcium gluconate injection solution) nebulizer treatments are commonly used in a similar manner at petroleum refineries, where HF is commonly used as an alkylation catalyst [36–38]. No controlled clinical trials prove better outcomes, but is standard practice in the petroleum industry and is recommended in the U.S. Agency for Toxic Substances and Disease Registry Medical Management of HF inhalation exposures [39] (Level III recommendation). The relatively benign nature of this treatment and the reported symptomatic relief after exposure to such a corrosive substance justifies its use.

Several authorities advocate systemic corticosteroids in acute RADS management [40] based on limited evidence in animal models [41]. Human case reports generally report use of inhaled steroids and some treatment guidelines advocate for inhaled steroids [42, 43]. Historically, intravenous steroids have been recommended after significant exposures to low solubility irritant gasses like phosgene [44] and oxides of nitrogen [45], since onset of severe lung injury and pulmonary edema are often delayed, even after significant exposures; it is theorized their use may prevent the late onset of pulmonary injury.

The author of the original case series on RADS recommends against systemic corticosteroids, but feels nebulized steroids are beneficial [27] (Level III recommendation).

Further information on this topic can be found in ► [Chap. 100, “Irritant and Toxic Pulmonary Injuries.”](#)

Inhalational Fevers and Hypersensitivity Syndromes

Inhaling a wide variety of organic and inorganic materials can cause a self-limited, flulike illness consisting of fever, chills, generalized body aches, and malaise. The prototypical occupational fever syndrome of this type is metal fume fever (MFF), but other exposures present similarly (see below). Patients frequently complain of headache, sore throat, chest pain, and cough and may have some dyspnea. There often is an elevated white blood cell count but generally no hypoxemia, radiographic abnormalities, or pulmonary infiltrates. The syndrome usually arises within a few hours after exposure and resolves within 1 day, with no residual effects. The mechanism may be an immunologic reaction in the alveolus, causing release of cytokines and immune mediators. Repeated exposures cause a “desensitization” or tachyphylaxis, whereby symptoms are worse at the beginning of the work week (“Monday morning fever”), and repeated exposures may elicit no symptoms at all.

Diagnosis is made based on the above-mentioned criteria, after ruling out influenza or other infectious causes. Treatment for inhalational fevers is supportive because this clinical entity is entirely self-limited. Proper education of the worker regarding the exposures that lead to this syndrome can prevent further episodes.

Many of the occupational settings where inhalational fevers occur also harbor risks of other acute lung injuries. Welding of stainless steel produces zinc oxide fumes responsible for MFF, but welding metal with cadmium can produce ARDS, and high-temperature arc welding in a confined space can cause significant NO₂ exposure leading to ARDS and subsequent risk of RADS. Farmers who unload silos may be exposed to silage that is contaminated with bacteria, grain, mold, cellular

debris, peptidoglycans, and glucans that can cause inhalational fever (“silo unloader’s disease” and *organic dust toxic syndrome* [ODTS]), but exposure to freshly stored silage can cause silo filler’s disease owing to liberation of NO₂ and causing ARDS. Farmers with moldy hay exposure may induce extrinsic allergic alveolitis (EAA, also known as hypersensitivity pneumonitis) as a result of exposure to the thermophilic bacteria that grow in wet hay.

In contradistinction to inhalational fevers, the ARDS due to EAA/HP often is accompanied by cough, dyspnea, hypoxemia, and pulmonary infiltrates on chest radiographs. Although fever is required for the diagnosis of inhalational fevers, fever may also be present in EAA/HP or in ARDS. The key distinguishing feature is that inhalational fevers have no chest x-ray abnormalities and usually no hypoxia, whereas chest x-ray abnormalities (typically ground glass opacities) and hypoxia are prominent features of ARDS and of EAA/HP. While repeated exposures to the causative agents of inhalational fevers cause a tolerance or significantly diminished response, repeated insults of EAA/HP may cause restrictive defects on pulmonary function testing due to interstitial edema and can lead to fibrosis and permanent restrictive lung disease. Attack rates after typical exposures for inhalational fevers are often greater than 80%, whereas EAA/HP occurs only in a small percentage of exposed individuals. Sensitization is required for the development of hypersensitivity pneumonitis, but this is not true for inhalational fevers. Repeated bouts of inhalational fevers due to certain materials (humidifier fever) may predispose individuals to the development of EAA/HP due to sensitization (see full discussion of EAA/HP below).

Metal Fume Fever. Heating metals above their melting point, such as while welding or torch cutting, causes formation of solid aerosols (fumes), often with accompanying oxidation. The resultant particle size of 0.1–1.0 μm easily reaches the alveoli, where an acute inflammatory cell response causes release of cytokines, producing the constellation of symptoms. The classic syndrome involves a metallic taste in the mouth, fever, rigors, headache, chest pain, and dyspnea with an abrupt onset 4–12 h after exposure.

Clinical tolerance to these effects occurs after regular exposure [46]. Zinc oxide fumes are the classic cause of MFF, and in the eighteenth century this was predominantly seen in brass foundries – hence the common name of *Brasser's Flu* or *Brass Founder's Ague*. More recently, MFF has been seen after welding galvanized steel, from the heating of zinc in the galvanized coatings [47, 48]. Limited epidemiologic evidence suggests that other metal fumes, such as the fumes produced when magnesium and copper are heated, can produce MFF [49, 50].

Polymer Fume Fever. Heating of polytetrafluoroethylene (PTFE, Teflon®) causes the formation of pyrolysis degradation products, the inhalation of which can lead to polymer fume fever. This fever occurs commonly when PTFE-coated metals are welded or flame cut. It also may occur after smoking cigarettes that are contaminated with PTFE resins from the hands of workers. This usually self-limited, flulike illness presents similarly to MFF, and diagnosis is based on the history of appropriate exposure. With prolonged exposures or when higher temperatures are involved, pulmonary involvement with accompanying chest x-ray findings of consolidation is possible [7]. There has even been a case of PFF reportedly due to exposure from burning of the PTFE coating of a nonstick frying pan [51].

Humidifier Fever. Humidifier fever is an inhalational fever syndrome of uncertain etiology associated with exposure to air contaminated by humidifier water that has excessive growth of microorganisms, most notably *Pseudomonas* and other gram-negative bacteria. It has similarities with HP (see below), but its high attack rates among exposed persons and benign course lend credence to the theory of an immunologic mechanism similar to MFF. Diagnosis is usually made only after numerous workers from the same building present with the appropriate signs and symptoms, and is one of exclusion. It occurs more often during winter months in cold climates, when these humidification systems are commonly in use, and nonsmokers are more susceptible than smokers. Humidifier fever is not to be confused with humidifier lung, which is a type of EAA/HP that occurs after long-term exposure to humidifier

contaminants. There may be considerable overlap of these entities [10, 52, 53].

Pontiac Fever. Pontiac fever can be thought of as a type of humidifier fever that is caused by exposure to water contaminated by *Legionella pneumophila*. In contrast to legionnaires' disease caused by the same organism, Pontiac fever is a self-limited, flu-like illness that has occurred after common source exposure to buildings with contaminated air-conditioning systems (County Health Department Building in Pontiac, Michigan, in 1968, hence the name). It also has been seen after *Legionella* contamination of indoor fountains, whirlpools, and spas [54, 55]. In contrast with Legionaire's disease, Pontiac fever has a high attack rate (<90%) among exposed persons, no associated pneumonia or infection, onset usually within 24–48 h after exposure, and is a benign self-limited fever syndrome; whereas Legionaire's disease is a pulmonary infection often associated with pneumonia and respiratory failure, has a low incidence among exposed persons (<5%, usually those with underlying respiratory illnesses), a longer incubation period, commonly requires hospitalization, and has a case-fatality rate of 5–30% [56].

Organic Dust Toxic Syndrome (ODTS) [57–59]. Organic dust toxic syndrome (previously called *pulmonary mycotoxicosis*, *grain fever*, and *silo unloader's disease*) is a catch-all term applied to a variety of inhalational fevers that occur after exposure to many different organic dust mixtures. Many of these dusts are associated with agricultural industries and include bacteria, fungi, grains, silage, hay, animal danders, pollen, and other complex mixtures. Responsible agents probably include bacterial endotoxins, fungal mycotoxins, cell wall debris, and peptidoglycans. Symptoms include fever, malaise, chest tightness, headache, cough, dyspnea, and generalized aches – usually beginning within hours of exposure. Hypoxia and chest x-ray abnormalities are typically absent, and the syndrome usually resolves without sequelae. There is a strong overlap, however, with the causative agents of EAA/HP, and in these exposure settings, ODTS is a diagnosis of exclusion after hypersensitivity pneumonitis is ruled out (see below).

Extrinsic Allergic Alveolitis. EAA (also known as hypersensitivity pneumonitis [HP]) is an interstitial lung disease probably caused by a combination of type III (humoral or IgG-mediated) and type IV (cell-mediated) delayed hypersensitivity reactions that occur after repeated exposure to a wide variety of antigens and some chemicals. It is felt that an exaggerated immune response occurs in genetically predisposed susceptible persons. Hypersensitivity pneumonitis most commonly has been associated with occupations with exposures to moldy organic materials, such as moldy hay (responsible antigen is actually a thermophilic bacteria) in Farmer's Lung and moldy grain in grain handler's lung. It has been estimated that between 1% and 19% of farmers exposed to moldy hay develop farmer's lung [60]. Many other EAA/HP syndromes are described and are named after the job or antigen exposures (see Table 4). It can even be seen in musicians due to heavy mold growth associated with salivary moisture in their horns and woodwind instruments. Animal handlers can develop EAA/HP secondary to exposure to animal proteins and excreta (such as pigeon breeder's lung), and between 6% and 20% of individuals exposed to bird droppings develop bird fancier's lung [66]. Exposures to various chemicals that cause occupational asthma (e.g., TDI, TMA) have also been implicated in causing EAA/HP [61, 67].

Outbreaks of EAA/HP have been reported in office buildings, the etiology of which was traced to air conditioning and humidification systems contaminated with bacteria and molds [53]. EAA/HP may occur in the home setting due to contaminated humidifiers or by pigeon or pet bird antigens. Due to its immune pathogenesis, there is a period of sensitization prior to developing the first reaction, which can be as long as months or even years. Acute symptoms, which occur 4–6 h postexposure and recur on challenge with the offending agent, include cough, dyspnea, chills, myalgia, fatigue, and high fever.

The pathophysiology of EAA/HP involves immune complex deposition in the lungs of sensitized individuals, with the resultant release of immune mediators and cytokines and inflammatory cell infiltration. Acutely, neutrophils are

involved, but later (or after repeated episodes) lymphocytes predominate, along with fibroblast recruitment. The typical presentation occurs 4–6 h after an intense inhalational exposure to the responsible antigen, and patients commonly have fever, chills, malaise, cough, and dyspnea. Chest x-rays are abnormal in about 80% of cases [68] and often have a reticulonodular pattern or reveal patchy infiltrates; patients are often misdiagnosed as having bacterial pneumonia due to inadequate history and failure to consider occupational or environmental exposures. There is usually hypoxia, and patients have crepitant rales on auscultation of the chest. The white blood cell count is elevated, as is specific IgG to the offending antigen, which can aid in the diagnosis (serum precipitins to specific antigens). The findings of reactive IgG antibodies to the specific antigen in itself is not diagnostic, however, since many asymptomatic similarly-exposed workers will have positive precipitins (40% of farmers; even higher in pigeon breeders), but only a small percentage develop disease. Smokers have less incidence than their similarly-exposed peers. Pulmonary function testing can be normal or may show a restrictive defect and a decreased diffusion capacity due to interstitial inflammation and edema. The acute episode usually resolves within 1–3 days. Initial treatment with corticosteroids is recommended along with removal from exposure and avoidance of further antigen contact to prevent future episodes. Repeated exposures often cause a worsening of the presentation, and tolerance, such as that seen in inhalational fevers, does not occur. Repeated low-level exposures cause a progressive, often irreversible, interstitial pulmonary fibrosis from interstitial collagen formation, along with occasional granuloma formation in about 30% of cases [67]. These patients may present from a typical occupational setting with the insidious onset of a constellation of signs and symptoms, including dyspnea, cough, weight loss, and fatigue. Chest x-rays may reveal increased interstitial markings and fibrosis, and pulmonary function testing usually shows restrictive disease and decreased diffusion capacity. Chronic EAA/HP may be clinically and radiographically indistinguishable from Idiopathic

Table 4 Serious illnesses, selected causative agents, and associated occupations/workers^a

Illness	Causative agent	Associated occupations/workers
ARDS (also possible late sequelae of RADS, BOF)	Irritant gases	
	Soluble gases	
	HCl, HF, H ₂ SO ₄ , HNO ₃ , NH ₃ , and other alkali and acid mists	Acid and alkali production workers; manure pit workers (NH ₃)
	SO ₂	Sulfuric acid production workers; air pollutant workers
	Tear gas	Law enforcement workers
	Isocyanates	Polyurethane industry workers, firefighters
	Insoluble gases	
	Phosgene	Polymer industry workers, welders, burning chlorinated metal degreasers
	NO ₂	Silo fillers, high-temperature arc welders
	Medium-solubility gases	
	Chlorine	Water purification workers, paper pulp workers, swimming pool workers
	Acrolein	Polymer industry workers, firefighters (component of smoke)
	Smoke inhalation	Firefighters
	Pesticides	
	Organophosphates, carbamates, type II pyrethroids, dinitrophenol, pentachlorophenol (wood preservative), paraquat	Farmers, exterminators, crop dusters, pest control workers, lumber industry workers
Acute toxic encephalopathy	Metals and metal compounds	
	Cadmium, mercury, manganese, Ni(CO) ₄	Smelters
	Lead	Lead-acid battery workers, HAZMAT site clean-up workers, lead reclamation workers, bridge painters, automobile radiator repair workers
	Mercury	Chlor-alkali workers (electrolytic production of chlorine and caustic soda), mercury-containing instrument manufacturers, fungicide users, topical antiseptics workers ^a
	Toluene, xylene, other hydrocarbon solvents	Painters, chemical production workers, solvent users (confined space)
	Simple asphyxiant gases (CO ₂ , CCH ₄ , propane)	Gas production workers, various workers with confined space issues
	Cyanide	Metal plating workers, jewelers, firefighters (smoke inhalation)
	Hydrogen sulfide	Farmers (manure pits), sewer workers, petroleum refinery workers
Acute hemolysis	Carbon disulfide	Viscose rayon workers ^a , rubber manufacturers ^a
	Carbon monoxide	Garage workers, firefighters, paint strippers (methylene chloride) (any exposure to incomplete burning, improper ventilation, or exhaust)
	Chlorates	Match and explosive production workers, dye manufacturers, paper pulp bleach manufacturers (ClO ₂)
	Arsine (AsH ₃), stibine (SbH ₃)	Workers with dopant gas for n-type semiconductors in the microelectronics industry
	Organic nitro and amino compounds	Synthetic dyes workers, leather and shoe industry workers, fabric dyers ^a

(continued)

Table 4 (continued)

Illness	Causative agent	Associated occupations/workers
Cyanosis	Methemoglobin-forming agents: organic amino and nitro compounds ^a	Synthetic dyes workers, leather and shoe industry workers, fabric dyers ^a
	CNS depressants causing hypoventilation and hypoxia	Various workers (see acute toxic encephalopathy above)
Hyperthermia/fever	Pentachlorophenol – wood preservative	Lumber production workers
	Nitrophenol pesticides, chlorophenoxyacetic acid herbicides	Exterminators, pest control workers, agricultural workers, farmers, forestry workers, landscapers
	Inhalational fever syndromes	See fume fever syndromes below
Seizures	Metals	
	Arsenic	Copper smelters, leather tanning workers, pesticides workers
	Copper	Copper smelters, miners
	Lead	Lead-acid battery workers, Hazmat site clean-up workers, automobile radiator repair workers, lead reclamation workers
	Manganese	Manganese miners, welders, chemical industry workers, metal refining workers
	Nickel	Workers in metal plating, coins, batteries, electronics, metal alloying industries
	Pesticides	
	Organochlorines ^a (lindane, cyclodienes, DDT), organophosphates, paraquat ^a , diquat (herbicides), pentachlorophenol, dinitrophenol, chlorophenoxyacetic acid herbicides	Farmers, agricultural workers, forestry workers, landscapers, pest control workers
	Rodenticides ^a (thallium, SMFA, strychnine, zinc phosphide, arsenic, methyl bromide)	Rodenticide users: granary workers, longshoremen, exterminators
	Phosphine, methyl bromide (fumigants)	Grain workers, pest control workers
	Any general CNS depressant producing hypoxia: toxic inhalants (CN, H ₂ S, carbon monoxide), simple asphyxiants (hydrocarbons, CO ₂ , He, N ₂), chlorinated hydrocarbons	See acute toxic encephalopathy above
Rhabdomyolysis	Any agent causing seizures (see above)	See above
	Any agent causing hyperthermia associated with hypermetabolic state (pentachlorophenol, dinitrophenol, chlorophenoxy herbicides)	Farmers, lumber industry workers, pest control workers, exterminators
	Carbon monoxide (direct cellular toxicity)	Workers who have any exposure to incomplete burning, improper ventilation, or exhaust: garage workers, firefighters; paint strippers (methylene chloride)
	Any CNS depressants causing coma and inducing rhabdomyolysis from pressure	See acute toxic encephalopathy above

(continued)

Table 4 (continued)

Illness	Causative agent	Associated occupations/workers
Fume fever syndromes	Metal fume fever	Welders (galvanized metal), foundry workers, smelting workers, metal refining workers
	Polymer fume fever	Welders (cutting through polytetrafluoroethylene coatings or polymer pipes), polymer workers
ODTS and other inhalational fevers	ODTS: Bioaerosols of fungi, bacteria, exotoxins	
	Moldy hay, moldy silage, compost	Farmers (“silo unloader’s disease”)
	Sewage sludge	Sewer workers, plumbers
	Grain dust	Grain mill workers (grain fever)
	Cotton dust	Cotton mill workers (mill fever)
	Animal confinement buildings	Veterinary workers, laboratory workers
	Other inhalational fevers	
	Contaminated humidifiers	Workers in any building with contaminated humidifiers (humidifier fever)
	Contaminated water cooling systems, spas, fountains	Workers in any building with contaminated cooling system or fountain (Pontiac fever)
	Contaminated wood dusts/chips/bark (moldy wood chip exposure)	Sawmill workers, pulp and paper mill workers, landscapers (“wood-trimmer’s disease”)
Hypersensitivity pneumonitis and Extrinsic Allergic Alveolitis	Organic antigen exposures	
	Moldy hay	Farmers (farmer’s lung)
	Moldy compost	Mushroom workers (mushroom worker’s lung)
	Contaminated humidifiers, dehumidifiers, HVAC	Office workers in any contaminated building (humidifier lung)
	Bagasse (moldy pressed sugarcane)	Sugarcane workers (bagassosis)
	Animal products (excreta, serum, feathers, dander)	Animal handlers (pigeon breeder’s disease, duck fever)
	Chemicals	
	Trimellitic anhydride, phthalic anhydride	Painters, epoxy resin users
	Diisocyanates	Polyurethane foam industry workers
	Plicatic acid (red cedar)	Red cedar workers, lumber industry workers, carpenters
	Pyrethrum insecticides	Exterminators, pest control workers, insecticide manufacturers
	Sodium diazobenzene-sulfonate (Pauli’s reagent)	Chromatographers
	Many others	Workers in varied industries
Myocardial infarction/ischemia	Carbon monoxide	Workers with exposure to exhaust or poorly ventilated combustion: miners, forklift operators, mechanics, firefighters
	Carbon disulfide	Viscose rayon workers ^a , rubber industry workers
	Organic nitrates	Explosive industry (TNT) workers
Cardiac arrhythmias		
Tachydysrhythmias	Chlorinated hydrocarbon	Mechanics, degreasers, dry cleaners
	Hydrocarbon solvents	Printers, painters, mechanics, degreasers, dry cleaners
	Carbon monoxide	Paint strippers (CH ₃ Cl), workers with exposure to exhaust or poorly ventilated combustion: miners, forklift operators, mechanics, firefighters

(continued)

Table 4 (continued)

Illness	Causative agent	Associated occupations/workers
Bradydysrhythmias	Organophosphates, carbamates	Farmers, pest control applicators
Acute renal failure	Arsine, stibine (due to hemolysis)	Semiconductor industry workers
	Halogenated hydrocarbon solvents (many)	Dry cleaners, degreasers, plastics industry workers
	Toluene (ATN)	Painters
	Any agent associated with rhabdomyolysis	See rhabdomyolysis above
	Cadmium	Welders
Acute hepatic failure	CCl ₄ , CBr ₄ , CHCl ₃ , other halogenated hydrocarbons	Mechanics, degreasers, dry cleaners, plastics industry workers
	Solvents: 2-nitropropane, DMF	Painters
	Dimethylacetamide	Textile workers

Data from Refs. [11, 61–65]

ARDS adult respiratory distress syndrome, *ATN* acute tubular necrosis, *BOF* bronchiolitis obliterans fibrosa, *CN* cyanide, *CNS* central nervous system, *DDT* dichlorodiphenyltrichloroethane, *HVAC* heating, ventilating, and air conditioning, *RADS* reactive airways dysfunction syndrome, *SMFA* sodium monofluoro acetate

^aMany of the chemicals/toxins no longer may be used or manufactured in the USA but are still in common use in other parts of the world. US industries with modern industrial hygiene practices have limited or eliminated many exposures to industrial toxins, but workers in other nations may remain at substantial risk

Pulmonary Fibrosis; a careful, detailed occupational history, serum precipitins to a specific antigen to which the patient is exposed, bronchoalveolar lavage, and histologic examination of lung tissue would likely all be needed to make the diagnosis.

Several authors have proposed specific diagnostic criteria for EAA/HP. These involve the presence of major and minor findings, including antigen exposure, specific antibodies, physical exam findings, presence of dyspnea, radiographic findings, pulmonary function testing including DLco, lymphocytic alveolitis on bronchoalveolar lavage, and lung biopsy findings, among others. None of these have been systematically evaluated. LaCasse (2006) has shown data that suggest the presence of several variables increases the odds ratio for predicting EAA/HP. Ranking from highest OR to lowest are: Exposure to a known offending antigen 38.8 (CI: 11.6–129.6); positive precipitating antibodies 5.3 (CI: 2.7–10.4); recurrent episodes of symptoms 3.3 (CI: 1.5–7.5); presence of inspiratory crackles 4.5 (CI: 1.8–11.7); onset of symptoms 4–8 h after exposure 7.2 (CI: 1.8–28.6); and weight loss 2.0 (CI: 1.0–3.9) [69].

Treatment of acute episodes of EAA/HP consists of administering oxygen and admission to the hospital when necessary. Corticosteroids are the only medications of any utility in the treatment of acute EAA/HP, but only have benefit in acute attacks. A single randomized, placebo-controlled trial [70] confirmed findings from other controlled but nonrandomized trials [62, 71] and from previous case series: the administration of corticosteroids can hasten the recovery from the acute stage of EAA/HP, but have no demonstrated effect on long-term prognosis and have no value in treatment of chronic EAA/HP, which is largely supportive. The decision to administer systemic corticosteroids should be guided by the severity of symptoms and physiologic abnormalities. Although the study above used 40 mg/day tapered over 8 weeks, higher doses such as prednisolone 1 mg/kg/day with a more rapid taper have been advocated more recently. The mainstay of treatment is withdrawal from exposures and strict prevention of any further contact with the inciting antigen or chemical [62, 69, 72] (Level 1 recommendation).

Miscellaneous Causes of ARDS. Exposures to metal fumes such as cadmium, manganese, and mercury can induce an MFF-like illness, which

then progresses hours later to acute chemical pneumonitis and pulmonary edema. This illness also can occur after exposure to gaseous metal compounds, such as nickel carbonyl, vanadium pentoxide, and zinc chloride [49].

Toxicants other than the above-described irritant gases can cause ARDS by altering pulmonary capillary membrane permeability. Fluid can leak into the alveolar air spaces with subsequent pulmonary edema. Examples are the pesticides dinitrophenol and pentachlorophenol. These toxicants act similarly to salicylates in that they uncouple oxidative phosphorylation, leading to a hypermetabolic state with fever, tachypnea, sweating, and pulmonary edema [73]. The acetylcholinesterase-inhibiting pesticides (organophosphates, carbamates) and nerve agents cause acetylcholine excess and can lead to cholinergic stimulation and muscarinic effects with copious pulmonary secretions and pulmonary edema, as well as acetylcholine-stimulated bronchial smooth muscle constriction. Neuromuscular blockade from the nicotinic effects of these insecticides can contribute to the respiratory failure and deaths associated with large exposures. Massive poisoning by a type II pyrethroid insecticide can cause pulmonary edema that has been mistaken for a reaction to an organophosphate. Subsequent atropine treatment was ineffective, and some deaths have occurred owing to atropine toxicity [74]. Aspiration of hydrocarbon solvents also can lead to pneumonitis and ARDS

Occupational Cardiac Toxicology

A variety of toxins encountered in the workplace can have deleterious effects on the heart (Table 4).

Myocardial Infarction

Carbon disulfide is the industrial toxin classically associated with accelerated atherosclerotic disease in workers. This property has been recognized since the 1800s and was well described in the occupational literature in workers with high

exposures in the rubber industry [20]. The mechanism by which carbon disulfide causes accelerated atherosclerosis is poorly understood but may be mediated by its propensity to inhibit various enzyme systems, and workers exposed to high levels have elevated total and LDL cholesterol. Workers exposed to high levels of carbon disulfide may have five times the incidence of coronary disease compared with nonexposed workers. However, at current recommended occupational levels, such as the threshold limit value (TLV) promulgated by the American Conference of Governmental Industrial Hygienists there appears to be no significant CV effects [75–77]. Carbon disulfide is also reported to cause peripheral neuropathies and neurobehavioral abnormalities at the very high exposure levels seen in the past [20].

Carbon monoxide is the leading cause of toxic deaths in workers worldwide. Chronic exposure is believed to accelerate atherogenesis, and acute exposures to high levels can induce myocardial infarction, vasospasm, and sudden death. Mechanisms and treatment of carbon monoxide poisoning are described in detail in ► Chap. 96, “Carbon Monoxide.”

Organic nitrates, such as nitroglycerin and ethylene glycol dinitrate, are used in the manufacture of explosives. Because they are well absorbed by inhalation and through the skin, workers can have significant systemic effects from simply handling or packing explosives. After a few years of exposure, the coronary vasodilatory effects of the nitrates are opposed by vasoconstriction. When organic nitrate exposure is withdrawn abruptly, the vasoconstriction is unopposed, and coronary vasospasm ensues with subsequent angina, myocardial infarction, or sudden death (“Monday morning angina”). Treatment is directed at reversing coronary vasospasm with calcium channel blockers and nitrates and prevention of further exposures [78].

Cardiac Dysrhythmia

Cardiac tachydysrhythmias can be caused by a variety of solvents, most notably chlorinated

hydrocarbon solvents, such as trichloroethylene (TCE), but they also can occur with aromatics (xylene, toluene), aliphatic hydrocarbons (naphthalene, gasoline), and chlorofluorocarbon refrigerants. These compounds sensitize the myocardium to the arrhythmogenic properties of catecholamines and in significant exposures can predispose the worker to tachydysrhythmias, syncope, and sudden death. Additionally, any toxin causing cellular hypoxia causes a subsequent tachycardia. This can include all the asphyxiants (carbon monoxide, hydrogen sulfide, cyanide, and simple asphyxiants) and any CNS depressant that causes hypoventilation and resultant hypoxia.

Cholinesterase-inhibiting pesticides, such as organophosphates, carbamates, and nerve agents, can cause effects secondary to an excess of acetylcholine and subsequent dysrhythmias. Depending on whether muscarinic or nicotinic effects predominate, tachycardia or bradycardia can be seen. There usually are other concomitant systemic signs of acetylcholine excess, such as *SLUDGE* (salivation, lacrimation, urination, defecation, gastrointestinal cramping, and emesis). There have been reports of QT prolongation and polymorphous ventricular tachycardia associated with these insecticides. These agents are described in detail in the Organophosphorous and Carbamate Insecticides and the Nerve Agents chapters. The metals arsenic and thallium have been reported to cause QT prolongation and torsades de pointes as well (see ► Chaps. 80, “Arsenic” and ► 85, “Thallium”).

Occupational Hepatic Toxicology

Many toxins encountered in the workplace have effects on the liver (see Table 4) because these xenobiotics are metabolized by the same hepatic enzyme systems that metabolize pharmaceuticals. In many cases, such as with methanol, ethylene glycol, benzene, and *n*-hexane, the parent molecules are not toxic but are metabolized into toxic compounds or highly reactive intermediates. These metabolites exert the toxic effects in humans. In many cases, chronic ethanol intake is

associated with an increased susceptibility to the hepatotoxic effects of these compounds, owing to P-450 enzyme induction. Many of the reported acute hepatotoxicities occur only after massive exposures. A wide variety of liver injury can be seen, however, after industrial exposures, including steatosis, cholestasis, hepatocellular necrosis, and vascular lesions [79, 80].

Halogenated Hydrocarbons

Halogenated hydrocarbons, primarily chlorinated hydrocarbons, are used mainly as solvents and degreasers. Many were used in the dry cleaning industry. The classic hepatotoxic chlorinated hydrocarbon is carbon tetrachloride (CCl₄). This compound is of historical interest because it was used widely as a solvent, degreaser, and fire extinguisher in the early twentieth century. After large exposures, such as inhalation in a confined space or intentional suicidal ingestions, carbon tetrachloride caused a centrilobular necrosis pattern similar to that seen with acetaminophen overdose. *N*-Acetylcysteine, the antidote for acetaminophen toxicity, and hyperbaric oxygen have both shown efficacy in animal models of CCl₄ poisoning, and favorable outcomes reported in case series. (Level III recommendation) CCl₄ is not used as widely today, having been replaced by other, less toxic products [81]. The main use of carbon tetrachloride today is as a chemical precursor for the manufacture of chlorofluorocarbons. Chloroform and carbon tetrabromide poisonings produce a similar pattern of hepatotoxicity. Other halogenated compounds, such as polychlorinated biphenyls and polybrominated biphenyls, have been associated with elevated liver enzymes and chloracne [82].

The primary degreaser and dry cleaning agent in the USA today is tetrachloroethylene (perchloroethylene). In large exposures, it may be associated with acute hepatic injury [83]. Related compounds, TCE, trichloroethane, and tetrachloroethane, also are hepatotoxic in large doses [84]. All these volatile compounds can cause CNS depression via a general anesthetic-type mechanism and can cause cardiac

dysrhythmias (see earlier). Their thermal breakdown products include phosgene and hydrogen chloride (see earlier section on irritant gases).

Solvents

The solvent 2-nitropropane has been associated with acute hepatic failure after confined space exposures in painters [85]. *N,N*-Dimethylformamide can cause hepatic injury and a disulfiram-like reaction with ethanol ingestion [87]. Dimethylacetamide is a hepatotoxin used in acrylic fiber production [87, 88]. Other petrochemicals have been implicated in liver injury [89].

Miscellaneous Compounds

Trinitrotoluene (TNT), an explosive, and elemental white phosphorus have also been reported to cause acute hepatic injury. Compounds associated with chronic liver disease and hepatic angiosarcomas (vinyl chloride monomer, arsenic) occur in the workplace but are not of concern to the intensivist. Copper causes chronic hepatic injury, but only in individuals who are genetically predisposed [65].

Occupational Renal Toxicology

Acute Renal Failure

Many of the industrial hepatotoxic compounds also are injurious to the kidney, the most notable being carbon tetrachloride. Renal failure is usually a consequence of acute tubular necrosis due to volume depletion from the hepatotoxic effects. Because P-450 enzymatic metabolism of xenobiotics also occurs in the kidneys, there can be direct nephrotoxicity as well [90]. Toluene is metabolized to hippuric acid which can induce an elevated anion gap metabolic acidosis after significant intoxication, but this is seen primarily with intentional abuse and not workplace

exposures. Renal failure has occurred secondary to acute tubular necrosis after toluene poisoning [91]. Other halogenated compounds associated with acute renal failure are chloroform, ethylene dichloride (solvent, fumigant), trichloroethylene (TCE), tetrachloroethane, vinylidene chloride (plastic intermediate), diesel fuel, and ethylene chlorohydrin (chemical intermediate) [92]. TCE can induce acute kidney injury, but only at very high long-term exposure levels [93], and chronic exposures at the levels associated with kidney injury are necessary before a risk of kidney CA is seen in workers [94]. Any compound that induces rhabdomyolysis can cause myoglobinuric renal failure (see Table 4). Treatment classically has involved ensuring adequate urine volume (with the use of mannitol) and alkalinization of the urine to prevent pigment deposition in the renal tubular cells. While there is theoretical rationale for the use of these agents, the clinical evidence is poor, and based on small studies with small sample sizes. A retrospective review studied over 2,000 patients in an ICU setting and found no efficacy for the use of either agent in preventing myoglobinuric renal failure. (Level II-2 recommendation) [95] Analogously, arsine and stibine gases cause acute renal failure because of hemoglobinuria induced by massive hemolysis. Exchange transfusions often are needed in addition to dialysis. Cadmium is associated with acute renal failure. Exposures in the industrial setting occur via torch-cutting or welding metals with cadmium coatings. Although chromium has been associated with acute tubular necrosis after massive oral exposures, these are not encountered in the workplace setting [96]. Arsenic, cadmium, and lead are known to induce chronic renal disease, and the effects of concomitant exposure to combinations needs further study [97]. By measuring LMW proteins (β -microglobulin, free retinol binding protein) in the urine of exposed workers, biomonitoring for early nephrotoxic effects is possible, but usually only as an epidemiologic tool [98]. In the USA, the Occupational Safety and Health Administration requires whole blood Cd, urine Cd, and urine β_2 -microglobulin monitoring of exposed workers [99].

Occupational Neurotoxicology

Central Nervous System

CNS depression caused by volatile solvents can occur in the workplace and is usually due to inadequate ventilation or confined space issues. The CNS depression is due to the general anesthetic properties of these compounds, since they act just like general anesthetic (GA) agents. Historically, many of these solvents, like TCE, were used as GA agents. Any hydrocarbon or halogenated hydrocarbon can produce these effects, even chlorofluorocarbon refrigerants and Freon (C). Many workers are at risk for this type of exposure, including painters; mechanics; heating, ventilation, and air conditioning (HVAC) personnel; and workers in a varied assortment of occupations in which these solvents are used (Table 5). A purported chronic toxic encephalopathy due to long-term exposure to solvents, known as painter's syndrome and initially reported in Scandinavian workers in the 1970s and 1980s, has been shown to be related to other factors, such as depression, low educational level, or chronic alcohol abuse, and not due to workplace exposures [100]. Many of these compounds, especially toluene and xylene, are inhaled intentionally for recreational use for their CNS depressant effects; and heavy users can develop a leukoencephalopathy (see below). Deaths have occurred in some cases owing to cardiac rhythm disturbances due to sensitized myocardium, as well as respiratory arrest due to over-sedation. The arrhythmias are seen especially with halogenated hydrocarbon abuse, and known as "sudden sniffing death." The malignant arrhythmia in these cases is felt to be due to endogenous catecholamine surge, such as from sudden startle/excitation response or heavy exertion/exercise while abusing. This catecholamine surge in the face of "sensitized myocardium" can initiate an "R-on-T phenomenon," and subsequent re-entrant arrhythmias, since these agents can delay repolarization. In addition, a chronic leukoencephalopathy can develop in chronic toluene abusers; recovery may occur after cessation of abuse. Toluene is also associated with a nonanion gap metabolic acidosis [101].

Methylene chloride (MeCl) is a unique chlorinated solvent that is metabolized to CO and can cause injury or death via GA effects, cardiac arrhythmias, or CO poisoning manifested as elevated carboxyhemoglobin concentrations. It is the only instance where carboxyhemoglobin levels can continue to rise after removal from the source of exposure. While well-known to cause life-threatening exposures to furniture strippers and factory workers, a relatively new source is from its use in bathtub refinishing. The products used are aircraft grade paint stripping products and usually contain high concentrations of MeCl (60–100%). In virtually all reported cases, deaths have occurred in small residential bathrooms, acting as confined spaces, and workers had inadequate ventilation and did not use proper air-supplied respirators. Since MeCl is heavier than air, concentrations in the tub can be orders of magnitude higher than the rest of the bathroom, right in the worker's breathing zone [102]. Treatment of cardiac arrest in these cases would necessitate deviation from standard acute cardiac life support protocols of using of epinephrine, since further arrhythmias can be precipitated by this agent in the sensitized myocardium; the use of beta blockers is suggested to reduce the possibility of R on T and further arrhythmias [103] (Level III recommendation).

Ethanol ingestion after TCE and trichloroethane exposure (and possibly other hydrocarbon solvents) induces a disulfiram-like reaction known as degreaser's flush, which may induce hypotension and subsequent syncope when alcohol is ingested after exposure. Any asphyxiant gas can cause CNS depression secondary to oxygen deprivation, including the simple asphyxiants, such as carbon dioxide, methane, and nitrogen, and the toxic asphyxiants, such as carbon monoxide, cyanide, and hydrogen sulfide (see earlier section on pulmonary toxicology).

Some occupational toxicants have been shown to cause CNS stimulation and occasionally seizures; these include the organochlorine insecticides DDT, cyclodienes, chlordecone, lindane, and related compounds [35–37]. Although most no longer are registered with the US Environmental Protection Agency and have been banned in

Table 5 Selected occupations and representative possible toxic exposures^a

Occupations	Possible toxic exposures
Agriculturalist, farmer	Pesticides, H ₂ S, CH ₄ , NH ₃ , CO ₂ , NO ₂ ; moldy hay (hypersensitivity pneumonitis), ODS agents
Artist	Cadmium, toluene, other HC solvents, lead glazes as in ceramics
Battery manufacturer/reclamation	Lead, cadmium, mercury
Beautician/cosmetologist	Persulfates, phenylenediamine, thioglycolates
Carpenter/lumberjack	Plicatic acid (western red cedar), multiple wood dusts, wood preservatives (PCP, chromium-copper arsenate)
Chromatographer	Sodium diazobenzene-sulfonate (Pauli's reagent)
Construction worker	Asphalt, PAH, solvents, paints, glues, wood dusts, lead
Dentist/hygienist	Amalgams (silver, mercury), nitrous oxide
Electrician	PCBs, lead (cable splicing)
Electroplater	Chromium, copper, lead, Ni, cadmium, solvents
Firefighter	CO, CN, acrolein, phosgene, HCl, HF, NH ₃ , NO ₂ , SO ₂ , isocyanates, hydrocarbons, PAH, smoke
Forester/landscaper	Wood dusts, wood preservatives (PCP, copper arsenate), pesticides, herbicides
Foundry worker/smelter/metal refining	Zinc, copper, lead, mercury (gold and silver refining), cadmium (zinc smelting), acrolein, arsenic, selenium (copper refining by-product)
Health care worker	Ethylene oxide, mercury, natural rubber latex, formaldehyde, glutaraldehyde, radioisotopes, x-rays, chemotherapeutics, blood-borne pathogens, anesthetic gases
Heating, ventilation, and air conditioning personnel	Lead (solder), contaminated water coolant systems (Pontiac fever), contaminated humidifiers (humidifier fever), natural gas, PAH
Highway worker	PAH (coal tar fumes), HC solvents, CO (exhaust)
Jeweler	CN, zinc, lead, solvents
Law enforcement personnel	Lead (firing ranges), CO (traffic exhaust), tear gas
Machinist	Cutting oils, solvents
Mason	CaOH (lime)
Mechanic/gas station attendant	CO, trichloroethylene, gasoline (HCs, benzene, MTBE, ethanol), lead
Mortician	Embalming fluids: formaldehyde, methanol, glutaraldehyde, isopropanol
Painter	TDI, solvents: toluene, xylene, turpentine, VOCs, CH ₃ Cl, lead
Paper pulp industry worker	Chlorine dioxide, chlorine, H ₂ S, SO ₂ , methyl mercaptan
Pest control/exterminator	Pesticides: organophosphates, carbamates, pyrethroids; HC solvents, herbicides, wood preservatives (PCP, chromium-copper arsenate)
Petroleum refinery worker	Gasoline, benzene, MTBE, PAH, ethanol
Plumber	Sewage, lead (solder)
Printer	Solvents: naphthas, toluene, xylene
Semiconductor industry worker	Dopant gases: arsine (AsH ₃), stibine (SbH ₃); gallium arsenide, diborane, phosphine, solvents, HF
Shipbuilder	Styrene
Shoemaker/repairer	Hexacarbons: n-hexane, methyl n-butyl ketone; solvents: benzene, toluene, cyclohexane
Textile worker	DMF, PTFE, dimethylacetamide, dyes; CS ₂ (viscose rayon)
Trucker	CO, diesel exhaust, lead
Veterinarians/animal handlers	Pesticides, animal dander
Welders	NO ₂ , phosgene, zinc oxide fumes (metal fume fever), polymer (polymer fume fever), lead, mercury, cadmium, chromium

CN cyanide, CO carbon monoxide, DMF N,N-dimethylformamide, HC hydrocarbon, HF hydrofluoric acid, MTBE methyl-tert-butyl ether, ODS organic dust toxic syndrome, PAH polycyclic aromatic hydrocarbons, PCB polychlorinated biphenyls, PCP pentachlorophenol, PTFE polytetrafluoroethylene, TDI toluene 2,4-diisocyanate, VOCs volatile organic compounds

^aMany of the chemicals/toxins no longer may be used or manufactured in the USA but are still in common use in other parts of the world. US industries with modern industrial hygiene practices have limited or eliminated many exposures to industrial toxins, but workers in developing nations may remain at substantial risk

Canada and Europe, developing nations still use these products extensively for pest control. Additionally, any agent that causes hypoxia or CNS depression to the point of hypoventilation can cause seizures by that mechanism (see Table 4).

Severe, acute poisoning by a few neurotoxins can induce a parkinsonian-like neurologic disorder. The most common such neurotoxin is carbon monoxide, which causes ischemic injury to the basal ganglia after severe poisoning episodes. Similarly manganese [104], carbon disulfide, and methanol have been reported to cause a parkinsonian-like syndrome. Lead poisoning can cause an acute encephalopathy with coma or seizures or both, primarily seen in the pediatric population. The same blood levels associated with lead encephalopathy in children from more chronic exposure due to pica are well tolerated in adult workers after short-term exposures; even levels exceeding 100 ug/dL (4.8 umol/L) can be seen in asymptomatic workers.

Mercury is well known to exert most of its toxicity on the CNS [105]. The most toxic form, methylmercury, was the cause of severe permanent CNS impairment in children in Japan, termed *Minamata disease*. Mothers ate fish contaminated with methylmercury from industrial wastes dumped in Minamata Bay [106]. The potency of other organic mercurials cannot be discounted. A chemistry professor in New England was reported to have suffered a fatal neurodegenerative disease from a seemingly trivial exposure to a few drops of a related compound, dimethylmercury, on her gloved-hand; the compound was being used as a nuclear magnetic resonance internal standard for mercury compounds. Aggressive chelation was ineffective and she died a few months after the incident [107]. Ethylene oxide is used as a gas sterilant for surgical equipment. It can cause CNS depression and peripheral neuropathy.

Peripheral Neuropathy

A wide assortment of toxicants have been associated with peripheral neuropathy, including the hexacarbons (hexane, methyl n-butyl ketone), carbon disulfide, acrylamide monomer, lead, arsenic,

thallium, mercury, and ethylene oxide. Certain organophosphates that inhibit the enzyme neuropathy target esterase induce a delayed myeloneuropathy called *organophosphate-induced delayed neuropathy*. This was seen during prohibition when alcoholics drank Jamaican ginger extracts contaminated with triorthocresyl phosphate (TOCP). More recently, there have been reports of occupationally-acquired organophosphate-induced delayed neuropathy [41]. Many older pesticides can cause chronic effects on the peripheral nervous system, owing to their heavy metal components, such as arsenic, lead, mercury, and thallium [108].

Occupational Hematopoietic Toxicology

Methemoglobinemia and Hemolysis

Many aromatic amino and nitro compounds are strong oxidizing agents. They are used as chemical intermediates, in the production of aniline dyes, and as accelerators and antioxidants in rubber production. These compounds can oxidize the ferrous iron in hemoglobin, causing methemoglobinemia (see ► Chap. 30, “Toxicant-Induced Hematologic Syndromes”). Nitrates from fertilizers, TNT, and naphthalene are other compounds that have been shown to cause methemoglobinemia. Chlorates, used in match and explosive manufacturing, can cause oxidation of the hemoglobin and denaturing of the protein molecule. The end result is methemoglobinemia unresponsive to the antidote methylene blue and, frequently, hemolysis. Arsine and stibine are semiconductor dopant gases that add a controlled amount of impurities to the silicon wafer to alter its electrical conductivity. Even brief exposures to these toxins can cause severe hemolysis, with subsequent acute renal failure and death in some cases [49].

Aplastic Anemia

Benzene is a well-known bone marrow toxin, exerting these effects through its electrophilic

reactive metabolite benzene epoxide. Exposures can cause depression of all blood cell lines, and it has been shown to be a cause of aplastic anemia and acute myeloblastic leukemia (AML). Other marrow toxins shown to cause aplastic anemia are ionizing radiation and chemotherapeutic agents (alkylating agents and antimetabolites).

The worldwide consumption of alcohol and alcoholism, or alcohol use disorder (defined as a “problematic pattern of alcohol use leading to clinically significant impairment or distress” by DSM-5) [1], are increasing [2]. This is particularly so among women as the social stigma surrounding drinking declines and alcohol is more readily accessible. Women are less likely to be diagnosed early and more likely to relapse after treatment.

Alcoholism is estimated to cause approximately 2.5 million global deaths annually (4 % of all-cause mortality) which mostly ensue from liver disease [2]. Approximately 90 % of alcoholics develop fatty liver, 25 % develop alcoholic hepatitis, 15 % develop cirrhosis and 10 % develop hepatocellular carcinoma [3, 4]. Alcoholic liver disease (ALD), especially cirrhosis, also accounts for increasing numbers of hospital admissions across the world, including ICU admissions [5, 6]. Each year about 26,000 patients with cirrhosis require ICU admission and support in the UK alone, which has a population of 60 million [7].

The risk of developing liver disease from alcohol relates to the daily dose and duration in years of exposure, together with other factors. The consumption of alcohol often is expressed in terms of *units* of ethanol ingested (Table 1). Drinking ≥ 30 g/day of ethanol increases the risk of ALD in both men and women [8]. Women have a greater risk of ALD than men, presumed due to differences in ethanol metabolism and distributional factors [9]. A retrospective study in men

Table 1 Calculation of units for alcohol^a

Type of drink	% Alcohol by volume	Volume	Alcohol content (Units)
Beer/lager/cider			
Alcohol-free	<0.05	440 mL	0
Low alcohol	0.5–1.0	440 mL	0.4
		1 pint	0.6
Standard strength	3.0–4.0	1 pint	1.7–2.3
Premium strength	5.0–6.0	1 pint	2.8–3.4
“Alcopops”	5.0–6.0	330 mL	1.7–2.0
Wine	8.0–13.0	750 mL	6.0–10.0
Fortified wines (e.g., sherry, vermouth)	14.0–20.0	750 mL	10.5–15.0
Spirits (e.g., gin, vodka, rum)	37.5–40.0	700 mL	26.3–28.0

^a1 Unit = volume % ethanol × 0.78

showed that 50 % of men with an average intake of alcohol of greater than 160 g per day for 20 years developed cirrhosis [10]. Later studies showed risk levels with alcohol consumption of 40 g per day for men [11]. Neither alcoholic hepatitis nor cirrhosis was seen in patients who consumed 160 g of ethanol per day for fewer than 5 years [10]. Abstinence from alcohol is critical in the ongoing management of patients and can reverse fatty liver, but not advanced ALD. Cofactors that worsen the risk of developing ALD include metabolic syndrome/obesity, type 2 diabetes mellitus, malnutrition, smoking, hemochromatosis, and chronic viral hepatitis B or C [9, 12].

The clinical diagnosis of ALD is made by a history of excessive alcohol consumption, together with active exclusion of other causes of liver disease. Important scoring systems for severity of liver disease include the Child–Turcotte–Pugh [13] (a semiquantitative score used to roughly characterize severity), MELD [14, 15] (a quantitative prognostic score based on serum bilirubin, creatinine, and INR – and a recent addition of serum Na⁺ [16] used to prioritize liver transplantation), and Maddrey discriminant function [17] using serum bilirubin and prothrombin time (to guide use of corticosteroids in alcoholic

hepatitis). Unfortunately the only definitive treatment of cirrhosis is hepatic transplantation.

Pathophysiology and Clinical Features of Liver Injury

Alcoholic liver injury seems to progress from fatty change through alcoholic hepatitis to cirrhosis, the full progression occurring in about 20 % of individuals [18, 19]. Alcoholic hepatitis develops in only a proportion of drinkers, even after several decades of alcohol abuse, and is assumed to be pre-cirrhotic, although not a required stage for progression [20].

Fatty liver is characterized histologically by microvesicles and macrovesicles of fat within the hepatocyte [18]. Most individuals with fatty liver are asymptomatic, although some have right upper quadrant pain or epigastric discomfort, nausea, or bowel disturbances [18]. Hepatomegaly is the most common clinical finding. The γ -glutamyl transferase and aspartate aminotransferase are usually high and the serum bilirubin modestly elevated in 20–30 % of cases. Alkaline phosphatase is elevated in about half of cases. Macrocytosis is commonly observed. Most lab results show marked improvement, if not complete reversal, with alcohol abstinence in a few weeks. The abdominal ultrasound shows an echogenic liver. Liver biopsy shows accumulation of triglycerides that may be mild, moderate, or severe in extent but is not routinely required for management purposes.

Alcoholic hepatitis is characterized by the presence of neutrophils in the lobules of the liver together with necrosis of hepatocytes [18]. The clinical presentation varies from hepatomegaly to jaundice, ascites, bleeding, and coma. Most patients with mild-to-moderate hepatitis on liver biopsy have anorexia, fatigue, lethargy, or epigastric pain [18]. Patients with severe hepatitis tend to present with jaundice, ascites, hemorrhage, or encephalopathy. On examination, patients may have ascites (60 %), bruising, and splenomegaly (15 %). Fever is a feature in 50 % of patients. Serum γ -glutamyl transferase and aspartate aminotransferase are increased and

higher than in other forms of alcoholic liver disease; 66 % of patients have increased serum bilirubin and alkaline phosphatase. More than half of patients are anemic, and macrocytosis is prominent. Patients with hepatitis often show a marked deterioration in their condition when admitted to the hospital.

Cirrhosis is defined as widespread fibrosis and nodule formation within the liver [18, 19]. It follows hepatocellular necrosis due to a variety of insults [18, 19]. The fibrosis disrupts hepatic architecture, impeding exchange of oxygen and nutrients through the basement membranes between liver cells and the blood and causing portal hypertension [21]. Cirrhosis usually is believed to be irreversible, but fibrosis has been shown to regress in hemochromatosis and Wilson's disease. The clinical spectrum of cirrhosis varies widely from asymptomatic hepatomegaly to hepatocellular failure to portal hypertension with ascites or variceal hemorrhage [18, 19]. Patients with alcoholic cirrhosis who are actively abusing alcohol are more likely to present with features of decompensation, owing to the superimposed hepatitis. The most common clinical sign is irregular hepatomegaly. Visible features of portal hypertension, such as collateral veins, are present in at least 60 % of patients. Clinical evidence of encephalopathy is seen in about one third of patients. Patients who are abstinent may show few laboratory abnormalities [21]. Plasma albumin concentrations are low in approximately half of patients, and macrocytosis is common [21].

While the diagnosis of the histological category above depends on liver biopsy, there are many noninvasive ways to diagnose alcoholic liver disease such as acoustic radiation force impulse imaging, shear wave elastography, MRI elastographic techniques (Fibroscan), and use of serum markers, all of which are covered in review [22, 23].

Low Platelet Count and Coagulopathy

Very low platelet counts often accompany portal hypertension (due to hypersplenism), despite relatively normal liver function tests [24]. There also are direct toxic effects of alcohol on both platelet

production and functionality [24]. The risk of bleeding is higher in patients with infection or coexistent abnormalities of coagulation.

The liver plays a major part in the control of hemostasis by producing vitamin K-dependent clotting proteins; factors II, VII, IX, and X; and proteins C and S. It also has a role in fibrinolysis by protein generation and clearance of active enzymes from the blood. Increased prothrombin time (PTT) is not usually seen in fatty liver or hepatitis. An increased prothrombin time is seen in alcoholic cirrhosis, as a result of decreased synthesis of clotting factors and increased fibrinolysis [25]. Interestingly, a relative decrease in liver production of anticoagulant factors offsets the increase in procoagulant factors in cirrhotics *with compensated disease*; thus, spontaneous bleeding is rare [7]. Thromboelastography (TEG) is a new approach to assessing such balance and importantly can be used to guide blood product replacement [7]. Even cirrhotic patients with a high PTT or INR can develop deep vein thrombosis [26] and in the absence of contraindications should have mechanical (but *not* pharmacological) prophylaxis [7]. Stable patients who are not bleeding and are not undergoing invasive procedures generally do not require therapy for coagulopathy. Patients who are actively bleeding need blood component therapy (red blood cells and platelets), fresh frozen plasma, and cryoprecipitate therapy, together with measures to control the bleeding. Fibrinolysis is common, assessed by TEG and treated with tranexamic acid when bleeding persists despite the measures above [Level V evidence]. When the PTT is very prolonged, protamine may assist in counteracting endogenous heparin-like compounds [Level V evidence] [7]. If patients present with GI bleeding, correction of coagulation abnormalities must also be accompanied by antibiotic therapy (IV ceftriaxone or oral norfloxacin) for up to 5 days [Level V evidence] [27].

Bleeding can complicate invasive procedures such as liver biopsy or invasive hemodynamic monitoring in patients with alcoholic cirrhosis. Risk of bleeding can be diminished by use of sites for insertion of catheters where pressure can be applied to the insertion site to control the bleeding (e.g., external jugular insertion of central

venous line rather than a supraclavicular or subclavian approach). Transthoracic liver biopsies should not be done when the prothrombin time ratio (PTR) or international normalized ratio (INR) is greater than 1.2. Safer alternatives include direct-vision laparoscopic liver biopsy with subsequent coagulation and transjugular liver biopsy, which can be carried out even with an PTR or INR greater than 3 [28]. Particular care must be taken with arterial blood gas sampling, and often insertion of an arterial catheter saves several attempts and reduces the risk of bleeding in patients in the ICU. Intramuscular injections should be avoided because of bleeding risk into muscle.

In the presence of coagulopathy or thrombocytopenia, the insertion of invasive catheters or intracranial pressure monitors should follow prophylactic administration of concentrated clotting factors or fresh frozen plasma, together with platelets if the platelet count is less than $50,000/\text{mm}^3$ [Level V evidence] [25]. Fresh frozen plasma which contains coagulation factors and inhibitors to fibrinolysis is effective for protection against bleeding and correcting the bleeding associated with alcoholic liver disease: it should be given until the measured INR or prothrombin time ratio is less than 1.2 [Level IIB] [29]. It does not contain activated clotting factors and does not precipitate or worsen the disseminated intravascular coagulation that can be seen in these patients [30]. Recombinant factor VII is a therapeutic advance that can fully correct coagulation and platelet function defects in cirrhosis and allow invasive procedures to be performed safely [Level IV] [31].

Infection is a precipitant for the coagulopathy of cirrhosis due to production of low molecular weight heparin-like substances [32]. Infection also increases portal pressure which adds to bleeding risks: thus, early administration of antibiotics reduces early bled rates of esophageal varices [Level IA] [33].

Hemodynamic Effects

Hepatic cirrhosis causes portal hypertension, which is thought to result from an increased resistance to portal venous blood flow through the liver

(backward resistance hypothesis) or from increased portal venous blood flow through the liver (forward flow hypothesis). When the portal circulation is obstructed by cirrhosis, a collateral circulation develops that returns portal blood into the systemic veins. The connection between portal and systemic circulations at the gastroesophageal junction is complex. Turbulent flow in perforating veins between the varices and the periesophageal veins at the lower end of the stomach may explain why esophageal variceal rupture is particularly frequent in this region [34].

In portal hypertension, submucosal arteriovenous communications develop between the muscularis mucosae and dilated precapillaries and veins [35]. This congestive gastropathy causes significant risk of bleeding, especially damage from aspirin or nonsteroidal anti-inflammatory drugs (NSAIDs) [35]. Paradoxically, this gastropathy may be increased after successful esophageal sclerotherapy [35]. Decreasing the portal pressure is the main intervention that stops bleeding in portal hypertension [Level I].

Patients with cirrhosis characteristically demonstrate systemic vasodilation and increased cardiac output [36] and are especially vulnerable to small decreases in arterial tone which precipitate hypotension. The greater the degree of hepatic decompensation, the greater the hyperdynamic changes. Several substances including bile acids, endothelins, glucagon, 5-hydroxytryptamine, nitric oxide, and prostaglandins have all been postulated to be vasoactive agents in such patients. What remains unclear, however, is how the vasodilation leads to the state of permanent high cardiac output and increased regional blood flow. The increased cardiac output is often associated with normal filling pressures, but cirrhotic patients have decreased myocardial contractility, which really becomes apparent when afterload is increased and the myocardium is stressed, i.e., "cirrhotic cardiomyopathy" [37, 38]. Alcohol is considered directly cardiotoxic [37, 38]. If surgery is contemplated in a patient with chronic liver disease, it is therefore important to formally assess the cardiac function by echocardiography first. This allows assessment of cardiac function, volume status, estimated right ventricular systolic pressure, and any right to left shunts (e.g.,

hepatopulmonary syndrome – see below) [7]. In patients with liver disease in the ICU, pulse contour systems provide measurement of cardiac output, stroke volume, and volume. Supra-arterial notch Dopplers can monitor changing volume status and cardiac flows. An invasive right heart catheter (e.g., Swan–Ganz catheter) assesses right heart function, pulmonary artery pressures, cardiac output, and pulmonary capillary wedge pressure.

The inotropic and chronotropic responses of the heart to β -adrenergic agonists are impaired in patients with cirrhosis. In one study, cirrhotics showed a nonsignificant increase in stroke volume with infusion of dobutamine [39]. The dose of isoproterenol required to increase the heart rate by 25 beats/min was three times higher in cirrhotics than in controls [40]. β -Adrenergic receptor density is reduced in cirrhotics, and importantly they may not manifest an appropriate tachycardia even when hemorrhaging [41].

Insertion of a transjugular intrahepatic portosystemic shunt (TIPS) (see later) may impair cardiac function and worsen the systemic hemodynamics in patients with cirrhosis [42]. Such patients have increased pulmonary capillary wedge pressure, diastolic dysfunction of the hyperdynamic left ventricle, and decreased systemic vascular resistance. TIPS reduces systemic vascular resistance further by diversion of blood through the splanchnic circulation, and a pronounced increase in central blood volume is seen [43]. TIPS insertion may therefore unmask a coexisting preclinical cardiomyopathy in patients with alcoholic cirrhosis [42].

Infection

A high index of clinical suspicion is needed to diagnose infection as it may be overt in patients with alcoholic liver disease. In patients suspected of infection, early use of broad-spectrum antibiotics (piperacillin/tazobactam) is recommended [Level IB] [44]. Infection may cause acute deterioration in liver function and is associated with poor clinical outcome [7]. The cytokines TNF α and interleukin-6 are key to the endothelial genesis of hepatocellular microcirculatory dysfunction

(characterized by higher portal pressures and reduced hepatic blood flow) that occurs in sepsis [7]. Bacterial infection is also a major risk factor in the development of renal dysfunction in cirrhosis, especially hepatorenal syndrome (see below). Regular surveillance for hospital-acquired infections is required and active measures are needed to prevent them.

A recent case series reports three patients with decompensated cirrhosis and invasive pulmonary aspergillosis (suspected because of worsening respiratory function and development of alveolar opacities) which proved fatal despite therapy with voriconazole [45]. Antigen and serology for aspergillus can be tested in blood and the organism in bronchoalveolar fluid samples.

Adrenal insufficiency is reported in 51–68 % of patients with cirrhosis (high Child–Pugh–Turcotte (CTP) score or MELD scores) and severe sepsis yielding hemodynamic instability and unsurprisingly is a poor prognostic factor [46]. Hydrocortisone treatment may improve survival in such patients, but should not be used unselectively in every ICU patient with cirrhosis [47].

Gastrointestinal Bleeding

Hematemesis from esophageal varices is the most common bleeding presentation of portal hypertension due to cirrhosis, although melena, without hematemesis, may occur from bleeding varices and portal hypertensive gastropathy (see earlier). Big, red varices bleed [48]. Esophageal bleeding is localized to the 5 cm above the cardia of the stomach [48]. This is the area in which sclerotherapy and band ligation, the treatments of choice for acutely bleeding varices, are directed [Level III] [48]. Variceal bleeding is a life-threatening complication of cirrhosis, and initial therapy is aimed at correcting hypovolemic shock and achieving hemostasis at the bleeding site and prevention of complications associated with bleeding (such as airway aspiration, encephalopathy, infections by enteric organisms, hypoxia, renal dysfunction). Excessive transfusion may occur with a consequent risk of continued bleeding or rebleeding [49].

Full discussion of the pharmacologic and endoscopic treatment modalities for acute variceal hemorrhage is beyond the scope of this chapter [50]. Octreotide reduces portal pressure and collateral blood flow and is effective in reducing blood loss and transfusion requirements as initial intervention which can be started quickly and as adjunct to endoscopic measures [Level IV] [51]. It does not have significant adverse effects [Level IV] [51]. Esophageal balloon tamponade is aimed at achieving temporary hemostasis by direct compression of bleeding varices. It is effective in controlling bleeding temporarily, but fatal complications occur in 6–20 % of treated patients, including aspiration pneumonia and airway obstruction [52].

Mortality from esophageal rebleeding is approximately 50 % within 6 weeks of the initial bleed [53]. The risk of rebleeding depends on the severity of the underlying liver disease and degree of portal hypertension. TIPS placement (see later) leads to lower recurrent variceal bleeding rates compared with controls [54]. In a recent meta-analysis comparing TIPS with endoscopic sclerotherapy for acute variceal bleeding, rebleeding in the TIPS group was lower than the sclerotherapy group [55]. However, the risk of developing hepatic encephalopathy was increased in the TIPS over the sclerotherapy group. There was no difference in survival time between the two groups [55].

Ascites

Portal hypertension due to cirrhosis is an important cause of ascites, i.e., detectable free fluid in the peritoneal space. Patients retain salt and water because homeostatic mechanisms become unbalanced, and the dysfunctional liver does not catabolize aldosterone efficiently, i.e., secondary hyperaldosteronism [56]. In the later stages of cirrhosis, there may be reductions in renal blood flow and glomerular filtration rate, as a result of vasoconstriction of the renal arteries. The kidney is less able to excrete free water because of reduced delivery of filtrate to the ascending loop of Henle and hypersecretion of antidiuretic hormone.

Ascitic fluid should be sent for analysis of cell count, total protein, and the serum-ascites albumin gradient (SAAG). A SAAG ≥ 1.1 g/dL supports the diagnosis of ascites due to portal hypertension [57].

The management of ascites is based on the combination of cessation of alcohol, a low-sodium diet (≤ 2 g/day), and the administration of oral diuretics, such as spironolactone (typically 100 mg/day). Resistant ascites often requires paracentesis, with intravascular albumin repletion (6–8 g of salt-poor albumin per liter of ascites removed) [58]. Resistant ascites (and acute esophageal variceal bleeding) has also been treated by insertion of a TIPS [59]. The flow across the shunt can be monitored by Doppler ultrasound and revised should occlusion occur. TIPS seems to be superior to large-volume paracentesis, improves renal function, and can improve the chance of survival without liver transplantation in patients with resistant ascites [Level III] [59]. Milodrine, an α -agonist, causes arterial vasoconstriction and improves the hemodynamics causing ascites [Level V] [60]. β -Blockers, ACE inhibitors, and $\alpha 2$ receptor blockers are no longer recommended in those with ascites as they cause systemic hypotension [58].

Renal Failure and Hepatorenal Syndrome

Most renal failure in cirrhosis is not due to hepatorenal syndrome and survival from all causes currently sits at 71 %. It is therefore important to actively seek sepsis and/or hypervolemia (secondary to GI bleeding, excessive diuretics, or GI fluid losses, e.g., diarrhea) as a cause of renal failure requiring active management [61]. Acute tubular necrosis is often due to a combination of nephrotoxic drugs, such as aminoglycosides, and intravascular depletion [61, 62].

Hepatorenal syndrome (HRS) is common in advanced cirrhosis and is characterized by renal failure due to marked renal hypoperfusion as the result of renal vasoconstriction as a result of arterial vasodilation in the splanchnic circulation [63, 64]. It is characterized by a progressive

increase in the serum creatinine >1.5 mg/dL, oliguria, and low urinary sodium (usually <20 mmol/L) in the presence of normal-sized kidneys and no other identifiable cause of renal failure (European Association for the Study of Liver Diseases). There are limitations to the value of creatinine as a marker of renal function in cirrhosis, and clearance of iohexol has been suggested as a suitable alternative. Pathological confirmation of renal disease such as transvenous renal biopsy is usually reserved for candidates for transplantation [65].

Historically the prognosis in HRS was 50 % alive at 1 month [66]. Management now includes rehydration, then albumin and terlipressin (a vasopressin analogue that improves the splanchnic circulation) [64, 67, 68], or albumin and octreotide plus midodrine [60] with better survival figures. Dialysis and subsequent joint hepatic and renal transplantation have resulted in survival of some patients. The development of HRS after spontaneous bacterial peritonitis (SBP) is best prevented by effective administration of albumin to patients who are hypoalbuminemic together with antibiotics (see the section on SBP for precise guidelines) [62, 69, 70].

Detailed management of hyponatremia is beyond the scope of this chapter but is the subject of a good review [71].

Pulmonary Abnormalities

Before anesthesia and surgery are contemplated, a complete assessment of the respiratory system of any patient with cirrhosis must be made. Many alcoholic cirrhotics are heavy cigarette smokers and develop emphysema, and as a result tidal volume, vital capacity, and functional residual capacity are reduced, and compensatory tachypnea may result in a respiratory alkalosis. Cirrhotic patients are also at higher risk of pneumonia [7]. Aspiration of blood or gastric secretions is particularly frequent in patients with impaired consciousness due to alcohol or hepatic encephalopathy. Prevention of aspiration is based on positioning patients safely, intubation in

comatose patients, and aspiration of gastric contents using nasogastric tubes. High risk includes during hematemesis, emergency endoscopy, and placement of balloon tamponade tubes. Aspiration pneumonia should be actively treated with antibiotics.

The incidence of pleural effusions is 5–6 % in cirrhotics with ascites [72]; 67 % are right sided, and 17 % are left sided. Small holes have been detected in the diaphragm by several methods [72, 73]. They usually respond to diuretics and salt and water restriction [72], but when large, thoracentesis should be performed. Rarely, pleurodesis or TIPS placement is necessary [72]. In any patient who abuses alcohol, but particularly in chronic alcoholics, pulmonary tuberculosis infection is common and must be excluded by chest X-ray and tuberculin testing.

In addition to the usual causes in the critically ill alcoholic, adult respiratory distress syndrome has been associated with sodium morrhuate sclerotherapy [74]. This sclerosant contains several toxic fatty acids and may affect pulmonary hemodynamics [74].

Chronic liver disease may also be complicated by hepatopulmonary syndrome (HPS) and portopulmonary hypertension (PPHTN). HPS is characterized by arterial hypoxemia caused by intrapulmonary vascular dilation in cirrhosis [75]. Symptoms are dyspnea and platypnea (shortness of breath on rising to an upright position). Screening is by blood gas analysis ($A-a$ gradient ≥ 15 mmHg), with diagnostic confirmation by transthoracic echocardiography with contrast enhancement by microbubbles seen in the left atrium. The only definitive treatment is hepatic transplantation, but patients can be managed on long-term oxygen therapy. Extracorporeal membrane oxygenation has been used as a bridge to transplantation in a single case report [76]. PPHTN is pulmonary hypertension in the context of portal hypertension. It is said to result from vasoactive substances reaching the pulmonary circulation via portosystemic shunts [77]. Symptoms are dyspnea, chest pain, and syncope. Screening is by transthoracic Doppler echocardiogram ($RVSP > 40$ mmHg), with

diagnostic confirmation by right heart catheterization (MPAP >25 mmHg), MPAOP <15 mmHg, and pulmonary vascular resistance >240 dynes cm^{-2} [75]. Management includes pulmonary vasodilation (IV and inhaled prostacyclin) and long-term oxygen therapy. Ultimately liver transplantation provides a cure.

Spontaneous Bacterial Peritonitis

SBP is a frequent complication in cirrhotic patients with ascites (incidence 7–23 % of hospitalized patients) and has a mortality of 30–50 % [78]. All hospitalized patients with ascites should have a diagnostic paracentesis performed, even if they are in the hospital for an unrelated reason. The diagnosis is made presumptively on the basis of abdominal pain or worsening ascites or a polymorphonuclear cell count in ascitic fluid greater than 250 cells/mm³. The organism responsible is isolated in 60–70 % of cases. This requires that samples be taken into blood culture bottles rather than sterile plastic universal tubes [79]. The current treatment of choice is cefotaxime 2 g every 8 h [Level V], but local antibiotic guidelines should be consulted. The remaining 30 % are considered culture negative but are still treated with antibiotics because of the risk of peritonitis and death if SBP is left untreated [79]. The SBP resolution rate ranges from 70 % to 90 %, and hospital survival is 50–70 %. Risk factors for persisting SBP include MELD score >25, SAAGb >1.5, and positive culture [80].

Despite the resolution of infection, SBP may trigger severe complications, such as renal failure, gastrointestinal bleeding, and hepatic insufficiency [81]. The development of hepatorenal syndrome after SBP can be prevented effectively by administration of albumin at a dose of 1.5 g/kg at the time of diagnosis, followed by 1 g/kg on day 3, together with antibiotics [Level IB] [69]. Prophylaxis against future SBP after the first episode should be undertaken with norfloxacin or trimethoprim/sulfamethoxazole [Mostly IA level evidence] [64]. Cirrhotic patients who present with bleeding should also receive SBP antibiotic

prophylaxis with either IV ceftriaxone or oral norfloxacin for 7 days [Mostly IA level evidence] [64].

Encephalopathy

Chronic hepatic encephalopathy is a potentially reversible complex neuropsychiatric disorder usually precipitated by dietary indiscretions or accumulation of toxic substances not cleared by the failing liver, GI bleeding, infections, hyponatremia, or use of sedative medications [82]. There are also changes to permeability in the blood–brain barrier, to neurotransmitter concentrations, and cerebral metabolism in patients developing encephalopathy. Characteristically it includes a triad of asterixis, confusion, and hyperammonemia. Encephalopathic stages are defined by the West-Haven criteria as 0 = normal, 1 = mild, 2 = lethargy, 3 = somnolence-to-stupor, and 4 = coma [82].

In patients who develop encephalopathy, it is important to exclude bacterial infections or gastrointestinal bleeding as a precipitant [83]. Most bacterial infections in cirrhotic patients are hospital acquired: urinary tract infections, SBP, respiratory tract infections, and bacteremia [84]. Encephalopathy is treated with lactulose to increase GI transit time and/or rifaximin [82, 85] to reduce ammonia production. In the case of deep encephalopathy, in addition to the above measures, oral intake is withheld for 24–48 h, and intravenous glucose and thiamine are given until improvement occurs. Enteral nutrition can be started if the patient appears unable to eat after this period; this is started at 0.5 g/kg/day and increased up to 1.5 g/kg/day gradually.

Abnormal Glucose Metabolism

Most patients with cirrhosis show impaired glucose tolerance [86], and there is a higher prevalence of overt diabetes in patients with cirrhosis than in the general population. Most are resistant to the effects of insulin, particularly on skeletal muscle. These patients also tend to have

hyperinsulinemia [87] because of a combination of increased insulin secretion and reduced insulin clearance (due to hepatocellular dysfunction or portosystemic shunting). Glucose intolerance is also surprisingly common in fatty liver associated with alcohol use.

Patients with postprandial hyperglycemia and minor increases of fasting blood glucose should be treated with a low-sugar diet. Tight blood sugar control is not desirable because of the risk of hypoglycemia; hence, keeping the blood glucose in the 140–180 mg/dL (8–10 mmol/L) range is desirable. If persistent postprandial glucose elevations are above this range, then the patient should receive an oral hypoglycemic. Biguanides however (e.g., metformin) should be avoided in patients with liver disease because they are at risk for serious drug-induced lactic acidosis. Sulfonylureas (e.g., tolbutamide and glipizide) can be used cautiously in alcoholic patients, but glibenclamide is best avoided because it can cause prolonged hypoglycemia. Patients who require insulin are managed with injections of short-acting insulin 30–45 min before each meal. Patients with liver disease are more prone to fasting and nocturnal hypoglycemia, and longer-acting insulins should be avoided.

Recent evidence demonstrates that a subclinical impaired glucose tolerance (and independently Child–Pugh B score and high MELD scores) was associated with lower survival in liver disease [88].

Muscle Wasting and Nutritional Deficiencies

Alcoholic liver disease is characterized by muscle wasting and nutritional deficiencies (e.g., vitamins A, D, E, and K) which are associated with increased morbidity and mortality [89–91]. Nutritional therapy helps to reverse these. Previously a protein-restricted diet was used to prevent hepatic encephalopathy, but the American Association for the Study of Liver Diseases (AASLD) and the American College of Gastroenterology currently recommend supplementation for nutritional deficiencies, frequent

interval feeds especially night and morning snacks, and enteral feeding for severe ALD [92]. A recent systematic Cochrane review however questions whether there is sufficient well-designed clinical trial evidence to justify this widely adopted clinical approach [91]. Such a diet would include 1.2–1.5 g protein/kg per day and 35–40 kcal/Kg [92]. However, the standard needs to be altered depending on the patient's race, their daily activity, degree of protein–energy malnutrition, glucose intolerance, and obesity [93]. Interestingly high body mass index (BMI) is an independent predictor of decompensation of cirrhosis, together with the hepatic venous pressure gradient and serum albumin concentration [94].

In those with protein metabolism disorder, branched-chain amino acid granules are often prescribed in addition to a 1.2–1.5 protein/kg diet [93]. The role of probiotics remains to be fully evaluated [95]. Tight sugar control is not desirable because of the risk of hypoglycemia; hence, a 140–180 mg/dL (8–10 mmol/L) range of blood glucose is desirable. Zinc replacement is often given to patients with cirrhosis at a dose of 20–50 mg elemental zinc three times per day [96]. There is not current evidence to support giving selenium replacement routinely.

Alcoholic Ketoacidosis

In alcoholic patients, metabolic acidosis can be due to lactic acidosis associated with sepsis or thiamine deficiency, alcoholic ketoacidosis (AKA), diabetic ketoacidosis, or methanol or ethylene glycol poisoning [97]. AKA occurs in alcoholics who have had a heavy drinking bout with subsequent vomiting, dehydration, starvation, and β -hydroxybutyrate-dominated ketoacidosis [98]. Awareness of the syndrome, together with taking a proper history, clinical examination, and routine laboratory tests, leads to the diagnosis [98].

AKA and toxic alcohol ingestion can be difficult to distinguish on initial presentation. A high osmolar gap (e.g., >25 mmol/L) associated with increased anion gap acidosis is a strong indicator of methanol or ethylene glycol intoxication but is not

specific, and history or analytic confirmation (e.g., blood β -hydroxybutyrate-to-acetoacetate ratios) is crucial in determining the cause [98–100]. Ethylene glycol and methanol poisoning are discussed in detail in chapters on these substances.

In addition to a history of diabetes or alcoholism, patients with diabetic ketoacidosis are characterized by higher plasma glucose concentration (32 mmol/L [576 mg/dL] versus 6.6 mmol/L [119 mg/dL]) and lower β -hydroxybutyrate-to-acetoacetate and lactate-to-pyruvate ratios compared with patients with AKA [101]. If the serum glucose level (in mmol/L) is less than the anion gap, the diagnosis of AKA should be considered [102]. The initial hormone profile is characterized by decreased blood insulin concentrations in both conditions.

AKA is a cause of unexpected death in a chronic alcoholic with little or no alcohol in the blood, increased acetone concentration in the blood, and no specific features on autopsy or toxicology [103]. The diagnosis often is missed unless it is sought out specifically by analysis.

The treatment of AKA is replacement of fluid, glucose, electrolytes (especially potassium), and thiamine. Insulin or sodium bicarbonate should be avoided [98]. Some patients have serious coexisting acute illnesses, and treatment of these is also essential.

Altered Drug Metabolism

Many factors determine the elimination of a drug, including its rate of absorption, distribution, plasma protein binding, and metabolism and elimination, particularly by the liver and kidneys. The extraction ratio of a drug across an eliminating organ can be calculated by the clearance. Drugs are classified as highly cleared by the liver (>70 % cleared at each passage through the liver), poorly cleared (<30 %), or intermediate [104]. Hepatic clearance has an important effect on the extent to which drugs become available in the systemic circulation when given orally. Highly cleared drugs have high “first-pass” removal and low systemic availability. The main factor

responsible for the reduced clearance of drugs metabolized by the liver in patients with cirrhosis is impaired ability of the liver to remove the drug from the blood. Possible mechanisms are intrahepatic shunts, portosystemic shunts, reduced amounts of drug-metabolizing molecules, and reduced hepatic uptake of drugs. The metabolic capacity of the liver is not a homogeneous entity but depends on the metabolic pathways involved. Oxidation (phase I) takes place in the centrilobular location [105] and is more prone to hypoxia and more affected in liver disease than conjugation (phase II), which is periportal in location and well preserved in liver disease [105].

Other mechanisms that could be responsible for altered drug kinetics in chronic liver disease include altered protein binding and acid–base or electrolyte changes. Many drugs commonly used in critical care units have reduced clearance or increased half-life in cirrhosis, e.g., ampicillin (give the normal dose), chlorthalidone (reduce the dose by 50 % and prolong the interval to every other day or every third day), diazepam (prolong the dose interval), furosemide (efficacy may be reduced due to low albumin, increase the dose), lorazepam (normal dose), and *N*-acetylcysteine (give normal dose) [104, 106–108]. A significant increase in half-life calls for prolongation of the dosing interval, whereas a decrease in clearance calls for a reduction of dose. Whether a dose reduction is necessary also depends on the toxicity of a drug. For adequate antibiotic coverage in a patient with SBP, the dose of cephalosporin does not require reduction. In contrast however for aminoglycosides, the dose and dosing interval must be reduced.

Other drugs have high clearance in cirrhosis (e.g., lidocaine (dose reduction), morphine (can be used in mild-to-moderate liver disease), metoprolol (normal dose)) [105, 108]. Even moderate cirrhosis significantly reduces the clearance of alfentanil, which also must be used with care [109]. Atracurium is the muscle relaxant of choice in liver disease because its metabolism is independent of hepatic metabolism, occurring by Hoffman elimination and ester hydrolysis [110]. Vecuronium is well tolerated by cirrhotics in

small doses, but with doses of 0.2 mg/kg, recovery is prolonged [110]. An increased volume of distribution in cirrhotic patients means that a higher dose of most muscle relaxants may be needed.

Isoflurane is the inhalational anesthetic of choice in liver disease because it undergoes minimal biotransformation, is least hepatotoxic, and maintains hepatic oxygen supply and uptake better than halothane or enflurane, although there have been reports of postoperative elevation in liver function tests even with this agent [111]. Halothane is best avoided because of its known hepatotoxicity, which, although rare, is unpredictable [112]. A recent meta-analysis showed that propofol produces more rapid and effective sedation and recovery than midazolam for endoscopy [113].

Adverse drug reactions frequently occur in patients with liver disease, and it is important to carefully consider any use of medication in these patients. Prostaglandin inhibitors, such as NSAIDs, including selective COX-2 inhibitors, reduce renal perfusion, particularly in patients who are intravascularly depleted, and may precipitate renal failure. Aminoglycoside antibiotics are particularly nephrotoxic in patients with liver disease [114]. They should be used only when absolutely necessary, and their use must be stopped if nephrotoxicity due to acute tubular necrosis develops. The inadvertent use of sedatives, analgesics, or diuretics can precipitate encephalopathy, hepatorenal syndrome, and gastrointestinal hemorrhage in patients with liver disease.

Alcohol Withdrawal

Obtaining an alcohol consumption history is crucial in identifying individuals at risk from withdrawal. Anyone who drinks more than 2–3 units/day (see Table 1 for calculation of units) is at risk from withdrawal, but usually it is clinically obvious with ceasing alcohol abruptly after routine ingestion of the equivalent of a bottle of spirits per day, which is characterized by autonomic hyperactivity and agitation/delirium [115]. Approximately 40 % of individuals who drink excessive amounts of alcohol, if hospitalized, have the potential to experience symptoms of alcohol withdrawal, and a high index of clinical suspicion and vigilance is required [115]. The differential diagnosis of acute alcohol withdrawal from other conditions is given in Table 2 [115].

Most patients who drink heavily manifest a minor withdrawal symptom complex of hyperactivity, hypertension, nausea, and tachycardia. Symptoms peak between 10 and 30 h and subside by 40 h after the last alcoholic beverage is ingested. Minor withdrawal symptoms often do not require specific therapy.

The early administration of benzodiazepines may prevent progression of the alcohol withdrawal syndrome and it remains the gold standard treatment for withdrawal [115]. Seizures may occur in the first 12–48 h and typically occur in bursts of two and can be treated successfully with diazepam (10–20 mg intravenously) or lorazepam (2–4 mg intravenously). Delirium tremens is

Table 2 Differentiation of acute alcohol withdrawal from other events altering consciousness levels

Parameter	Alcohol withdrawal	Wernicke's syndrome	Subdural hematoma	Hypoglycemia	Hepatic encephalopathy
Consciousness level	Awake but agitated	Variable	Fluctuates	Variable	Reduced
Hallucinations	Yes	Yes	No	No	No
Anxiety	Yes	No	No	Yes	No
Speech	Rapid, incoherent	Slurred (cerebellar)	Normal	Slurred	Slurred
HR/BP	Raised	Tachycardia, BP normal	Slow pulse, hypertension	Tachycardia, hypotension	Normal
Sweating	Yes	No	No	Yes	No

Table adopted, with adaptation, from Ref. [116] (Data from Mayo-Smith MF [117])
BP blood pressure, HR heart rate

Table 3 Clinical Institute Withdrawal Assessment of Alcohol Scale Revised [119]

Components of the scale
Nine items scored on a scale of 0 (no symptoms) to 7 (most severe symptoms)
Nausea or vomiting, tremor, paroxysmal sweats, anxiety, tactile disturbances (itching, numbness, bugs under the skin), auditory disturbances (sensitive to sound, hallucinations), visual disturbances (sensitivity to brightness, hallucinations, headache, agitation)
One item scored on a scale ranging from 0 (no symptoms) to 4 (disorientated to place or person)

characterized by coarse tremors, agitation, fever, tachycardia, profound confusion, delusions, and hallucinations [118]. Delirium tremens occurs in <5 % of individuals withdrawing from alcohol and starts 60–80 h after the last alcoholic beverage, lasting from 1 to 8 days [117, 118]. Hyperpyrexia, ketoacidosis, and profound circulatory collapse may develop, and if untreated, the syndrome carries a mortality of 15 % versus 1 % in patients who are treated [116, 117].

Benzodiazepines (chlordiazepoxide, diazepam, or lorazepam) are good pharmacologic treatments for alcohol withdrawal, including delirium tremens. The duration of action, rapidity of onset, metabolism, and cost of the specific agent determine the choice of agent. Dosage should be individualized, based on withdrawal severity scores, comorbid illness, and history of seizures [115, 117]. As a guide, the daily doses employed in the early phase of management are chlordiazepoxide, 100 mg; diazepam, 40 mg; and lorazepam, 8 mg, with much higher dose needed for severe cases. Little or no modification of dose is needed in minimal liver disease, but if there is significant liver disease, the initial dose of longer-acting benzodiazepines should be reduced by about 25 %.

An alcohol withdrawal rating scale, e.g., Clinical Institute Withdrawal Assessment of Alcohol Scale [119], is used to monitor time course and severity of clinical symptoms (Table 3). On this scale scores below 8 rarely need withdrawal medications [118], 8–15 need modest benzodiazepines, and scores above 15 indicate close monitoring of alcohol withdrawal seizures and delirium tremens, especially if the systolic BP is

>150 mmHg or there is tachycardia [118]. There is good evidence that pharmacologic management of alcohol withdrawal is effective [116, 117]. Pharmacologic management of alcoholism, however, is only one component of the management of alcohol withdrawal. Provision of a calm, quiet environment, reassurance and attention to fluid and electrolyte disorders, and comorbidities are equally important.

The management of delirium tremens the management includes control of seizures etc with benzodiazepines in a safe environment [120]. Severe withdrawal may necessitate ICU admission and use of propofol or barbiturates [115]. Other drugs such as β -Blockers and α_2 agonists (clonidine and dexmedetomidine) can be used as adjunctive therapy to relieve some of the more distressing autonomic symptoms and delirium that accompany alcohol withdrawal [115, 117, 121]. Use of carbamazepine, sodium valproate, baclofen, gabapentin, and ketamine remains under investigation for AWS [115, 122, 123].

Patients receiving treatment for alcohol withdrawal also should receive group B vitamins (intravenously or orally). The administration of vitamin B₁ (thiamine) prevents Wernicke's encephalopathy (characterized by confusion, ataxia, nystagmus, and short-term memory defects). In patients where Wernicke's encephalopathy is suspected, the recommended doses of thiamine are 500 mg IV tds for 5 days, with multivitamins [124]. Thiamine is discussed in greater detail in the chapter on that agent in the "Antidote" section. Alcohol withdrawal is discussed further in another chapter (► Chap. 27, "Withdrawal Syndromes").

Prognostic and Ethical Considerations for Acute Deterioration of Patients with Alcoholic Liver Disease and the ICU

Acute deterioration of patients with chronic liver disease presents as multiple organ failure requiring admission to ICU. Alcoholic hepatitis and variceal hemorrhage are common precipitants [7]. Management focuses on preventing further deterioration in liver function, reversing

precipitants and supporting failing organs. Artificial and bioartificial liver support systems have not yielded significant improved survival in such patients, and for a select few hepatic transplantation provides better survival [7].

Historically patients in an ICU with chronic liver disease and critical illness had a mortality of >60 % [125, 126] or >89 % [127]. A more recent report including more than 16,000 ICU patients with cirrhosis in the UK found an overall mortality of 65 %, and this rose to 90 % with sepsis, if >1 day of renal and respiratory support were needed [128]. In contrast in a less highly selected group of patients with chronic liver disease (i.e., two nonliver transplant centers), the ICU mortality rates of 38 % were reported [6].

Prognosis is determined by the number of organs failing (SOFA score), the presence of infection, and the degree of liver dysfunction (Child–Turcotte–Pugh or MELD) [7]. EASL guidelines recommend organ support for patients with pre-morbid MELD <15, but not if the MELD is >30 and there are ≥ 3 organs failing [128]. The problem is that in acute illness, MELD can change significantly [6]. Thus, it appears that liver-specific scoring systems alone are less accurate in predicting outcome than the more generic scoring systems alone (e.g., simplified organ failure assessment (SOFA) or APACHEII) [129], and estimates of survival appear more predictive if used after 48 h of supportive care [130]. It is therefore vital to concurrently use the three predictors articulated by Olson et al. [7] together to determine the prognosis [130]. In essence, it is our ability to manage the underlying acute illness that is the critical prognostic factor [5] and hence determines the appropriateness or otherwise of ICU care.

If a patient deteriorates in ICU (e.g., their vasopressor requirement escalates, ventilatory support needs to be significantly increased, or they develop unresolvable acidosis), this normally indicates the need to discuss with the family a decision either not to increase therapy or withdraw it. EASL guidelines recommend that “the persistence of 3 or more organ failure after 3 days spent in ICU” should lead to withdrawal of treatment [128]. Ideally end-of-life wishes and

care are pre-planned and discussed with the patient with chronic liver disease and their family prior to acute deterioration and the possible need for ICU admission. Palliative care can be used early in terminal illness together with life-prolonging therapies [131].

Along with active supportive care, judicious gastrointestinal decontamination, and antidotal therapy, elimination enhancement techniques should be considered in the comprehensive management of any poisoned patient. Elimination enhancement techniques are defined as any procedure that accelerates the endogenous clearance of poison already absorbed and located either in the blood or tissue compartment. Corporal techniques provide their effects inside the body and include multiple-dose activated charcoal (MDAC), resins, and urine pH manipulation, as discussed elsewhere. Extracorporeal treatments (ECTRs) occur in a circuit outside the body (with the exception of peritoneal dialysis) and include hemodialysis, hemoperfusion, hemofiltration, and plasma exchange [1]. As the prognosis of most toxic exposures remains excellent with supportive measures alone, only a small minority of poisonings benefit from active elimination enhancement; for example, MDAC, urine alkalization, and hemodialysis were only used in 0.06%, 0.5%, and 0.1%, respectively, of patients reported to the US poison control centers [2]. Although the large proportion of the literature reviewing the efficacy of elimination enhancement techniques is derived from human case reports, evidence-based and consensus-based recommendations are now available for extracorporeal treatments [3–16].

Principles and Factors Influencing Poison Removal During Extracorporeal Treatments

The elimination of a poison by an ECTR depends on its physicochemical and pharmacological properties as well as the modality chosen for removal and the operational settings of the technique. Extracorporeal elimination of a poison is only possible if all of the following are present: (1) it can be extracted from the blood compartment, (2) a significant proportion of total body stores can be eliminated, and (3) extracorporeal clearance contributes to a significant extent to endogenous clearance. The first condition is dependent on the molecular size and protein binding of the poison, and it is correlated to the extraction ratio (ER) which can be calculated as $(A-V)/A$, where A represents the inflow (or prefilter) plasma concentration and V represents the outflow (or postfilter) plasma concentration. An extraction ratio of 1.0 implies complete elimination of a poison from the plasma through the extracorporeal circuit. The second condition relates to its volume of distribution (VD), and the third depends on the relative importance of ECTR versus endogenous clearance of poison.

Therapy-specific factors to consider include the process of poison removal (e.g., diffusion, adsorption, convection) as well as the parameters chosen for a specific technique such as the dialysis membrane (dialyzer surface area, membrane pore structure), characteristics of the filter/cartridge, rate of blood flow, and rate of effluent flow [17].

Poison-Related Factors

Molecular Size

Poisons with a molecular size below 1,000 Da will be removed by any of the three processes but best by diffusion. Poisons larger than 1,000 Da will be better removed by convection or adsorption [18], although present-day hemodialysis is usually capable of clearing poisons with a size up to 10,000 Da. Hemofiltration can remove poisons up to 50,000 Da. Poisons with very large molecular sizes (>100,000 Da) can only be removed by

adsorption (hemoperfusion) or by centrifugation/separation (Therapeutic plasma exchange).

Protein Binding

Poisons that are extensively bound to serum proteins cannot be removed significantly by hemofiltration and hemodialysis as the size of the poison-protein complex exceeds that of the pores of the hemofilter/dialyzer. During hemoperfusion, however, the adsorbent column (activated charcoal or resin) competes with plasma proteins for the poison and can therefore be an option for removal of protein-bound poisons. These principles are not universal; for example, in toxic concentrations, there may be saturation of the protein binding sites (e.g., valproic acid), increasing the fraction of unbound poison, which then can be more readily removed by hemodialysis. Further, if the binding constant of the poison to protein is low, the removal of the unbound poisons will result in rapid dissociation of the bound portion, resulting in a continuous pool of dialyzable substrate; phenytoin is one such example [19].

Volume of Distribution

A poison's volume of distribution is the apparent volume into which it is distributed at equilibrium assuming no clearance has occurred and assuming the body is a single compartment of homogenous water. The volume of distribution may be calculated by dividing the total poison content in the body by its concentration in the blood compartment.

Drug and poisons that distribute extensively in tissue (e.g., tricyclic antidepressants, digoxin) have a high VD. Conversely, those that distribute in total body water (e.g., methanol) have a $VD = 0.6\text{--}0.7$ L/Kg, while those exclusively confined to the blood compartment (e.g., rituximab) have a $VD = 0.06$ L/Kg. As ECTRs only remove poisons from the intravascular space, ECTR will not significantly enhance elimination of poisons with a high VD. For example, due to its low protein binding (25%) and relatively low molecular size (780 Da), digoxin easily crosses the dialyzer; however, because of its high VD (5–7 L/kg), less than 5% of total body burden of digoxin will be removed in a 6-h dialysis session. Many publications still erroneously conclude that a poison with

a high volume of distribution is amenable to extracorporeal clearance solely based on a high clearance or a rapid reduction of serum concentrations [20, 21]. Rarely, ECTR may be considered for poisons with a high VD: examples of these include situations where the poison has not yet fully distributed into tissues [5] and those where the toxic compartment is the blood [22].

Endogenous Clearance

Extracorporeal removal will not be useful if endogenous clearance of a poison (via metabolism and native elimination routes) far outweighs that which can be obtained via ECTR [23]. For example, because the hepatic clearance of lidocaine ($>1,000$ mL/min) greatly exceeds the clearance obtained with dialysis (150 mL/min), extracorporeal elimination of lidocaine is never indicated. This is also true of many street drugs. Any impairment in endogenous metabolic and elimination route will lower the decisional threshold to initiate dialysis, as the relative contribution of ECTR clearance versus endogenous clearance will become greater.

ECTR-Related Factors

Factors specific to the ECTR which affect poison elimination include the process of removal, characteristics of the dialysis membrane (i.e., material, surface area, porosity), the concentration gradient across the membrane, the blood flow rate through the dialyzer, and the dialysate/ultrafiltrate flow rates. Some hemoperfusion cartridges become saturated after a few hours and need to be replaced [24]. These characteristics are discussed later in this chapter where the different extracorporeal modalities will be further described.

Available Extracorporeal Treatments to Enhance Elimination of Poisons

Processes of Poison Removal

These can usually be classified by their process: diffusion (hemodialysis, peritoneal dialysis), convection (hemofiltration), adsorption

(hemoperfusion), centrifugation/separation (therapeutic plasma exchange) [17, 25].

Diffusion (Hemodialysis)

During diffusion, poisons transfer passively from one compartment (blood) to another (dialysate), separated by a semipermeable membrane down a concentration gradient (Fig. 1a). Dialysate flows countercurrent to the blood flow. Characteristics of a poison that is removable by diffusion are a low molecular size ($<10,000$ Da) and a low protein binding ($<80\%$). Specific components of the dialysis system will impact poison clearance; these include membrane type, its surface area, and blood and dialysate flow rates (Table 1). The development of synthetic high-flux and high-efficiency membranes now permit removal of larger poisons which were considered nondialyzable 20 years ago [18]. Increasing both the rates of dialysate and especially blood flow result in greater diffusion and elimination of the poison and should therefore always be maximized in poisoning situations [17].

Convection (Hemofiltration)

During convection, solute and solvent are removed by solvent drag and substituted by a physiological solution (Fig. 1b). Unlike diffusion, this process requires energy via a hydrostatic pressure gradient. Compared to diffusion, convective transport allows removal of poisons with larger molecular size (up to 50,000 Da) but performs slightly worse for smaller poisons [17]. Because most common poisons have a low molecular size ($<1,000$ Da), convection does not offer any advantage over diffusion for the majority of poisonings.

Adsorption (Hemoperfusion)

During adsorption, blood circulates through an extracorporeal circuit equipped with a charcoal or a resin cartridge onto which poison is trapped (Fig. 1c) [26]. Unlike diffusion, adsorption is not as limited by molecular size, lipid solubility, or protein binding of the poison. Alcohols and most metals, however, are poorly adsorbed to columns.

Fig. 1 Mechanisms of poison removal during ECTR (During diffusion, poison follows a concentration gradient. During convection, poison and solvent are eliminated

actively by a pressure gradient. During adsorption, poison is trapped within the cartridge. Notice that larger poisons do not get cleared as well during diffusion)

Table 1 Summary of extracorporeal treatments

ECTR	Process	Molecular size cutoff (Da)	Protein binding cutoff	Relative cost	Complications	Comments
Hemodialysis	Diffusion	<10,000	<80%	+	+	Corrects uremia and acid–base/E+ disorders
Hemoperfusion	Adsorption	<50,000	<95%	++	+++	Saturation of cartridge
Hemofiltration	Convection	<50,000	<80%	++	+	Corrects uremia and acid–base/E+ disorders
Therapeutic plasma exchange	Centrifugation/ Separation, Filtration	<1,000,000	None	+++	+++	
Albumin dialysis	Diffusion, Adsorption	<300,000	None	++++	++	Liver replacement support
Exchange transfusion	Centrifugation/ Separation, Filtration	None	None	++	++	Easier in neonates, corrects hemolysis
Peritoneal dialysis	Diffusion	<10,000	<80%	++	++	

All extracorporeal treatments above are less likely to be useful for poisons that have a high VD or a high endogenous clearance

Specific Extracorporeal Treatments

Hemodialysis, Hemoperfusion, and Hemofiltration

Worldwide, extracorporeal treatments are mainly used for the treatment of kidney failure. Hemodialysis and peritoneal dialysis are the preferred modalities for end-stage renal disease, while hemodialysis and continuous renal replacement therapies are usually preferred for acute kidney injury. In poisonings, intermittent hemodialysis has several distinct advantages over other extracorporeal modalities [27]: poison removal occurs rapidly, it corrects many complications associated with severe poisonings – acute kidney injury (AKI), volume overload, acid–base abnormalities, electrolyte disturbances, and even hypothermia. Hemofiltration provides all of these advantages but is less available as an intermittent therapy.

In contrast, hemoperfusion does not correct uremia or electrolyte disorders, requires more systemic anticoagulation than dialysis, and is limited to blood flows <350 mL/min because of the risk of hemolysis [28]. Furthermore, cartridges cost

severalfold more than dialyzers and need to be replaced every 2–4 h, as they become saturated. Finally, new dialysis membranes provide poison clearances comparable to that achieved by the best adsorbent columns. For example, clearances for both theophylline and phenobarbital, poisons for which hemoperfusion was historically considered superior to dialysis, can easily reach > 150 mL/min with dialysis [26, 29, 30]. For these reasons, hemodialysis is generally preferred in almost all settings where hemoperfusion is indicated [26]. These considerations are reflected by historical trends in ECTR choice for poisonings (Fig. 2) [31–34].

Adverse events and risks associated to ECTRs are relatively uncommon; systemic hypotension is often reported although this is usually encountered in patients with renal failure who require fluid removal. As poisoned patients rarely require fluid removal, the likelihood of hypotension is probably most related to the effect of the poison rather than the ECTR itself. The incidence of complications for hemoperfusion is higher, although these are usually reversible [30]: the nonselective adsorption of certain cells and

Fig. 2 ECTR trends in the USA from 1983 to 2014 (The Y-axis is a logarithmic scale)

molecules result in a fall in the concentration of platelets ($\cong 30$ – 50%), white blood cells ($\cong 10\%$), serum fibrinogen, fibronectin, calcium, or glucose [35, 36].

Continuous Renal Replacement Therapy

Continuous renal replacement therapies are popular modalities for the management of AKI. Continuous renal replacement therapies are a heterogeneous classification of ECTRs that share common characteristics: they are most often dispensed in the ICU setting, their blood and effluent flow are usually lower than those provided by intermittent therapies, and they are prescribed continuously until the patient recuperates or expires. Continuous renal replacement therapies include continuous arteriovenous hemodialysis, continuous venovenous hemodialysis, continuous arteriovenous hemofiltration, continuous venovenous hemofiltration, continuous arteriovenous hemodiafiltration, and continuous venovenous hemodiafiltration. Venovenous therapies have for the most part replaced arteriovenous therapies as they only require 1 dual-lumen catheter (instead of 2 single lumen catheters for

arteriovenous therapies), are not as dependent in systemic blood pressure, and have a lower incidence of thrombosis and embolization.

The role of CRRTs in the management of acute poisonings remains uncertain [37]. The solute clearance with continuous modalities is usually two to three times lower than that attained by intermittent therapies. Further, the hemodynamic benefits of CRRTs in poisoned patients are limited as net fluid removal is rarely required, unless AKI or pulmonary edema also develops. Although it has been suggested that CRRT may be preferred to avoid the sudden increase in poison concentration seen after discontinuation of intermittent therapies (“rebound”), the benefit of this remains uncertain, unless rebound is caused by ongoing absorption of poison from the gut.

Peritoneal Dialysis

There is little role for peritoneal dialysis in acute poisoning. It is an inefficient method of toxin elimination, achieving a maximum clearance of 10–15 mL/min (less than one tenth of that achievable by hemodialysis) [25]. Peritoneal dialysis has no advantages over the other extracorporeal

treatments in poisoning situations, although it may still be considered in the case of infants in whom hemodialysis may be too cumbersome to perform.

Therapeutic Plasma Exchange and Plasmapheresis

Plasmapheresis is a process in which plasma is separated either by filtration or centrifugation from withdrawn blood, and formed elements are retransfused back to the patient. In therapeutic plasma exchange (TPE), the removed plasma is discarded and replaced by 5% albumin, fresh-frozen plasma, cryoprecipitate-poor plasma, or stored plasma. Clearance during TPE is limited to 50 mL/min [25, 38]. The role of TPE in the treatment of acute poisoning is not well defined, but this method should only be considered for poisons which are very highly protein-bound (>95%) or in poisons that are larger than the accepted cut-offs for hemofiltration or hemoperfusion (>50, 000 Da) [39–41]. Adverse outcomes from TPE involve complications associated with placement of the vascular access, bleeding, hypocalcemia, and hypersensitivity reactions to the replacement plasma proteins [42, 43].

Exchange Transfusion

Exchange transfusion is a treatment in which apheresis is used to remove the patient's red blood cells and replaced with transfused blood products. Its role in poisoning is unclear but may be considered in poisons that cause massive hemolysis (e.g., sodium chlorate), in resource-poor settings where no dialysis machinery exists, or in infants, as it is technically less cumbersome to use than hemodialysis in this population.

Extracorporeal Liver Assist Devices (Albumin Dialysis)

Extracorporeal liver assist devices are ECTRs designed to replace failing liver function in the context of acute hepatitis and cirrhosis, especially as a bridge to liver transplantation or remission. There are several variations of these devices, but they all share a common principle in that an albumin-containing effluent competitively

competes with serum proteins for binding of poison. Theoretically, these devices are more performant at removing albumin-bound poisons than classical diffusive and convective techniques. However, preliminary clearance data does not show any superiority of these techniques in poisonings to theophylline, valproic acid, or phenytoin [44–46]. Because these procedures are expensive (>\$8000 per treatment in the USA) and seldom available, their application for poisoning situations remains unknown. Table 1 summarizes the various extracorporeal treatments available for poison removal.

General Indications for Extracorporeal Removal of Poisons

The EXTRIP (EXtracorporeal Treatment In Poisoning, <http://www.extrip-workgroup.org/>) workgroup [3, 4] have published guidelines for the use of blood purification for 16 key poisons [5–10, 12, 15, 47, 48]. For poisons not covered by these clinical recommendations, a comprehensive risk assessment that includes weighing the cost-benefit ratio for ECTR is required, which can be summarized in Fig. 3.

Absolute indications for ECTR include the following (all must be present) [27]:

1. *The poisoning exposure must be severe.* The exposure to a specific poison must be significant enough to warrant the cost and complications associated with ECTR. Obviously, a patient with life-threatening clinical signs (status epilepticus, respiratory depression, ventricular dysrhythmias), especially if prolonged, will classify as severe. In rare cases, a poison may produce delayed effects (methanol, paraquat); monitoring of levels might therefore predict future clinical compromise and would prompt *prophylactic* ECTR, i.e., before the appearance of toxic effects.
2. *There must be an absence of life-saving alternatives.* Rarely, an antidote may either amend or prevent the apparition of toxic effects related to a poison. Extracorporeal purification then becomes less crucial or indicated. This is the

Fig. 3 Decisional process to the use of an ECTR in a poisoned patient (Reproduced with permission from Seminars in Dialysis: Ghannoum, M., et al. (2014). "A stepwise

approach for the management of poisoning with extracorporeal treatments." *Semin Dial* 27(4): 362–370)

case for acetaminophen poisoning, when N-acetylcysteine is available. Because ECTR is somewhat invasive and may require transfer to a specialized center, its cost and benefit should be weighed against those of the antidote.

3. *The ECTR must be capable of removing the poison from the blood compartment.* The poison to be removed should permeate readily through the dialysis membrane or the column. This relates to a high extraction ratio and a high extracorporeal clearance (see above).
4. *The ECTR must be expected to significantly contribute to total body clearance.* As shown previously, if a poison is mostly confined outside of the intravascular space (high V_D), or if it is extensively and rapidly metabolized by endogenous routes, ECTR will likely not be removing poison from the body to a proportion that justifies its initiation.

A proper risk assessment requires weighing potential benefits of the ECTR to its complications. Some exposures are associated with a high risk of short-term mortality (e.g., salicylates $> 500 \text{ mg/kg}$, paraquat), while others may cause irreversible tissue damage (e.g., blindness for methanol). In other situations, ECTR will expectantly reduce the length of mechanical ventilation and immobilization (e.g., barbiturates, carbamazepine). Finally, there may be situations where ECTR will likely not affect outcome but may reduce hospitalization and associated costs (e.g., dialysis versus fomepizole in a methanol poisoned patient without metabolic acidosis) [49, 50]. Any of these benefits should be weighed to potential adverse events associated to ECTR; in general, these are minimal and limited to the traumatic insertion of a vascular access (which can be minimized with ultrasonographic guidance) [51]; more rarely, ECTR can potentiate elimination of

certain antidotes [52] and/or precipitate withdrawal symptoms if drug levels fall below the therapeutic range [53]. Costs of a single dialysis, including equipment and nursing/physician fees, are minor compared to the cost of a day in the ICU. In the absence of any clinical outcome data, studies should demonstrate significant drug removal, or, at a minimum, molecular characteristics that may predict extracorporeal removal.

Practical Considerations

A double-lumen central catheter is required for administering most forms of extracorporeal treatments. A temporary femoral catheter is often preferred, using ultrasound guidance to limit complications and ensure patency [54]. To maximize efficacy, the largest surface area dialyzer should be used. Heparinization of the circuit is favored to prevent clotting of the extracorporeal circuit unless there is a significant risk of bleeding. The blood flow and dialysate/effluent flow should be maximized for optimal clearance [17].

Poisoned patients may not share the same metabolic profile as those with renal failure; it is therefore important to tailor the composition of the dialysate to the requirement of the poisoned patient to avoid dangerous imbalances. This may include adjustment of the concentration of calcium, phosphate, magnesium, potassium, and/or bicarbonate.

A single 6-h extracorporeal treatment will usually suffice to substantially lower blood levels of most xenobiotics. When significant toxicity is present or suspected to be prolonged, there is little risk to extend this for several more hours (hemoperfusion cartridges may need to be replaced because of saturation).

Patient disposition

Many poisoned patients die prior to initiation of dialysis [55]. If the risk assessment suggests that a

patient may require dialysis, prompt communication with a center that can dispense acute dialysis and even prophylactic transfer to one may be required, even if the patient does not yet meet criteria for blood purification. Because significant delay may occur between the time a decision is taken to perform ECTR and the time when it is initiated, the dialysis personnel should be rapidly contacted and a temporary dialysis catheter installed as early as possible. If an admission to the ICU is required, the patient should be placed in a bed that has the required water canalization for dialysis. In special circumstances (e.g., nursing, logistics), a clinician may prefer the lesser efficient CRRT over intermittent dialysis if the former can be initiated sooner.

Following ECTR, serial poison concentrations and clinical status should be monitored for a period long enough to account for redistribution or ongoing absorption ($\cong 12\text{--}24$ h). The catheter should remain in place until the physician is convinced that additional sessions are unnecessary. Factors to consider when deciding if the catheter can be removed are the position of the catheter, the likelihood of the need for further ECTR, the risks of infection, and the complications of replacement of the catheter if needed.

Poisons Amenable to Extracorporeal Elimination

In the large majority of poisoning cases, ECTRs are not required. In fact, the drugs or poisons that are most commonly responsible for poisoning-related fatalities (e.g., opiates, stimulants, tricyclic antidepressants, and “street drugs”) are not effectively amenable to extracorporeal removal. Poisonings that are most likely to benefit from extracorporeal removal include those by: salicylates, lithium, methanol, ethylene glycol, valproic acid, biguanides, and theophylline. In special circumstances, poisoning to carbamazepine, acetaminophen, isopropanol, methotrexate, barbiturates, or paraquat may necessitate

Fig. 4 Pictorial summary of EXTRIP recommendations

treatment with an ECTR. The EXTRIP workgroup has provided recommendations for several poisons, the summary of which are presented in Fig. 4. Specific indications will be covered in detail in the following chapters.

Epidemiology of Toxic Deaths

The understanding of the epidemiology of poisoning deaths remains difficult for several reasons. Many comorbid factors contribute to the outcome, including the patient's age, underlying medical condition, and the delay between exposure and treatment. The literature on poisoning deaths does not reflect the true prevalence. A major discrepancy exists between hospital and nonhospital deaths, and there is a wide variation according to the sources of reporting. The main sources of information in the United States are the data collected by the Toxic Exposure Surveillance System (TESS) of the American Association of Poison Control Centers and by the National Center for Health Statistics (NCHS) [1, 2]. There are marked differences between these two data sets [2]. Fatalities are underreported to poison control centers, and the NCHS data set gives a larger profile of poisoning deaths by reporting more out-of-hospital deaths.

In 2013, 43,982 poisoning deaths were recorded by the NCHS, and only 1552 deaths were recorded by the TESS [1, 2]. In these data sets, the relative distribution of death circumstances differed for unintentional drug poisonings, unintentional nondrug poisonings, and intentional poisonings. The death rate associated with drug poisoning has increased in the USA by roughly 300% over the past three decades and is now the leading cause of injury death exceeding the number of motor vehicle traffic deaths. Fig. 1 Rates of deaths from drug poisoning and drug poisoning involving opioid analgesics – United States, 1999–2013 <http://www.cdc.gov/nchs/data/databriefs/db166.htm>

data from the National Vital Statistics System reveal that from 2000 through 2013, the age-adjusted rate for drug-poisoning deaths involving heroin nearly quadrupled from 0.7 deaths per 100,000 in 2000 to 2.7 deaths per 100,000 in 2013 [3]. During the same period of time (1999–2013), the drug poisoning death rate more than doubled from 6.1 to 13.8 per 100,000 population, and the rate of drug poisoning deaths involving opioid analgesics nearly quadrupled from 1.4 to 5.1 per 100,000 [4] (Fig. 1). Benzodiazepines were also present in a significant number of opioid-analgesic poisoning deaths.

Most cases reported to poison control centers are not managed in a health care facility [3]. In 2013, of 2,188,013 human poison exposure cases, 99,117 (4.5%) were admitted to critical care units. On the same number of exposures, only 1552 fatalities (0.07%) were reported [2]. Human exposures with more serious outcomes have increased by 4.7% per year since 2000. The top five substance categories associated with reported fatalities were: sedative/hypnotics/antipsychotics, cardiovascular drugs, opioids, stimulants and street drugs, and alcohols.

There are limited statistical reports specifically addressing intensive care unit (ICU) mortality rates.

The ICU and in-hospital mortality of poisoned patients is generally described as low. There is a variability according to the type of poisons and the sample of the population that is analyzed. A small American retrospective study found an ICU mortality rate of 2.7%, while a larger German study showed a mortality of only 0.2% in patients younger than 65 years, whereas patients older than 65 years had a mortality of 2.2% [5, 6]. The in-hospital and long-term mortality of ICU patients admitted with an acute intoxication was recently analyzed in Dutch hospitals on a large population sample [7]. The ICU mortality was 1.2% and the in-hospital mortality was 2.1%. The mortality 12 and 24 months after ICU admission was 6.5% and 9.3%, respectively, and was relatively low compared with other ICU admissions. The adjusted observed mortality showed that intoxications with street drugs have a significantly higher mortality 1 month after ICU admission [7].

Mechanisms of Death

Death may be the consequence of the direct or indirect action of a toxic substance on an isolated organ (target organ) or on the whole organism. For

example, the lung is the target organ in paraquat poisoning; progressive respiratory failure develops within a few days or weeks after exposure, with evident pathologic lesions. Mortality also exists, however, with toxins that do not have lesional effects. Outside the hospital, death due to acute poisoning is mainly the result of central nervous system (CNS) depression with subsequent cardiorespiratory failure. CNS depression is the mechanism of toxicity for opiates and most psychotropic drugs. Under these circumstances, death usually is related to the lack of early supportive treatment. Early cardiocirculatory failure, before hospital admission or a few hours after, is another common cause of toxic death. It is observed not only with cardiotropic drugs, such as calcium-channel blockers and digoxin, but also with other substances, including cocaine, colchicine, and chloroquine. Delayed complications, such as infection, renal failure, hepatic failure, and respiratory failure, may account for late mortality in the ICU.

Brain death is encountered less commonly after acute poisoning. The early recognition of this condition by critical care physicians leads to major decisions, such as care withdrawal and organ donation. A first question to be answered is the possible mechanism of brain death in this setting. Brain death cannot be the sole consequence of anoxia due to unsuccessful resuscitation because pure anoxia seldom gives rise to brain death except when associated with brain edema leading to acute intracranial hypertension. In our experience, brain edema consistently preceded brain death in poisoned patients in whom a cerebral computed tomography scan was performed. Brain edema classically is said to be from a vasogenic or cytotoxic origin. The first mechanism is illustrated by hepatic encephalopathy in the case of acetaminophen poisoning (Fig. 2) [8]. Cytotoxic brain edema may be caused by numerous metabolic disorders. It has been documented after intoxications by some anoxic agents (CO) or following profound hypoglycemia in the case of insulin overdose [9]. Extremely severe metabolic acidosis is likely responsible for irreversible brain damage (with associated brain edema) in the case of methanol or ethylene glycol poisoning [10–12]. Ionic disorders and

Fig. 2 Major brain swelling in a 30-year-old woman who presented with fulminant hepatic failure after acetaminophen overdose

hyperthermia have been reported to contribute to cerebral edema associated with the use of 3,4-methylenedioxymethamphetamine (Ecstasy) or other substances leading to the serotonin syndrome. Ionic disorders may be related to the inappropriate secretion of antidiuretic hormone [13]. The clinical picture usually is complicated by other disorders, such as autonomic instability or disseminated intravascular coagulation. Finally, epileptogenic substances may provoke irreversible brain injury after status epilepticus.

Intracranial hypertension also may be the result of focal anatomic lesions. Extensive neuronal destruction with hemorrhages was found at post-mortem examination in an autopsy study of 28 patients who died from methanol poisoning [14]. In a personal observation of fatal methanol poisoning, extensive hemorrhagic necrosis originating from the basal ganglia was observed (Fig. 3). In methanol-poisoned patients investigated by magnetic resonance imaging, the putamen preferentially is involved [10]. The lesions can be edematous and fully reversible at the early stage or, in some instances, can become hemorrhagic and necrotic. These lesions are probably

Fig. 3 Extensive hemorrhagic necrosis originated from the basal ganglia in a 32-year-old man who died as a result of acute methanol poisoning

due to the combination effects of tissue acidosis and hypoxia-ischemia status. Cerebrovascular accidents, including subarachnoid hemorrhage, intracerebral hemorrhage, and cerebral infarction, have been reported with increasing frequency in association with cocaine use. Although most patients have evidence of underlying cerebrovascular disease, reports have failed to show underlying disease in some patients [15–18]. These observations illustrate the need to obtain brain imaging when irreversible brain damage is suspected after acute poisoning, because functional disturbances are considerably more frequent than anatomic lesions.

Diagnosis of Brain Death in Poisoned Patients

The accuracy of the brain death diagnosis is crucial in cases of poisoning [19–22]. With concurrent misleading conditions (hypothermia, drugs, metabolic disturbances), the brain death diagnosis

should be verified by using a reliable, accurate, and safe confirmatory test. Even if brain death is primarily a clinical diagnosis, confirmatory tests are required. In the case of brain death, the confirmatory tests show the absence of cerebral blood flow (four-vessel arteriography, radioisotopic technique, and transcranial Doppler) or the absence of electrocerebral activity (electroencephalogram [EEG], multimodality evoked potentials [MEPs]).

Cerebral four-vessel angiography remains for most authors the confirmatory test of choice to determine brain death. Cerebral angiography has a high accuracy because cerebral blood flow cannot be abolished completely by any toxic substance and gives clear-cut results in misleading conditions. Angiography cannot be performed at the bedside, however, and cannot be repeated easily. It can cause deleterious effects, which may be found ethically unacceptable if one considers that the prognosis of a patient presenting with barbiturate overdose with transient isoelectric EEG can be excellent. Depending on the mechanism of acute brain injury, there may be some discrepancy between EEG findings and cerebral angiography when diffuse cerebral anoxia is not followed by major brain edema formation [23].

Brain scintigraphy with ^{99m}Tc -HMPAO technique has been used in brain death diagnosis. Clinical conditions such as hypothermia or metabolic coma exhibit no, or little, effect on brain ^{99m}Tc -HMPAO uptake. Few data are available concerning the use of cerebral angioscintigraphy for the diagnosis of brain death in poisoning [24–26]. Facco and colleagues [27] investigated 50 deeply comatose and brain-dead patients by single-photon emission computed tomography (SPECT). In this series, a cerebral circulation test was mandatory by law. In the 21 patients in whom brain death could not be diagnosed properly by EEG and clinical examination owing to the presence of associated factors (e.g., sedation, drug intoxication), SPECT showed brain perfusion arrest in 15 patients on the first test and in six patients on retesting. These six last patients had residual weak perfusion of the basal ganglia, thalamus, and/or brainstem that totally disappeared within 3 days. This illustrates that SPECT

findings were closely related to the dying process by rostrocaudal deterioration.

Positron emission tomography has not been used to a significant extent in brain death diagnosis owing to practical difficulties. Only two reports have been found in the literature from 1988 to the present [28, 29]. The reports showed the absence of significant intracerebral fludeoxyglucose uptake or retention in three cases and one obvious case of clinical brain death. In the second report, a slow rise of tracer was noted over time within the sagittal sinus, providing a false-negative scintigraphic evaluation for brain death diagnosis.

Transcranial Doppler is also a helpful method of estimating cerebral blood flow. This modality is more dependent on examiner skill and the patient's anatomic features, however. The results are not influenced by the action of sedative drugs.

EEG is by far the most often used confirmatory test for brain death diagnosis. Nevertheless, EEG is sensitive to hypothermia, drugs, and metabolic disorders and is of little help in the case of poisoning or other misleading conditions. The possible occurrence of reversible isoelectric EEG has been documented in hypothermia and with several drugs, including barbiturates, methaqualone, diazepam, meprobamate, and trichloroethylene [30–38].

Evoked potentials may offer significant advantages over EEG. Evoked potentials are a minimally invasive technique largely used for many years in the operating room and in the ICU. Numerous conditions that may influence electrophysiologic testing have been studied extensively [39]. In all cases of suspected brain death, the general policy of our institution is to use the combination of EEG and MEPs (flash visual evoked potentials [VEPs], somatosensory evoked potentials [SEPs], and brainstem auditory evoked potentials [BAEPs]) to confirm brain death [39–43]. MEPs are recorded easily and rapidly at the patient's bedside and evaluate the brainstem and the cerebral cortex. The three-modality evoked potential pattern of brain death is highly specific and associates the disappearance of all cortical and brainstem activities to the persistence of retinal, peripheral, and spinal activities (Fig. 4). It is unequivocal in most situations mimicking

brain death. Only the association of a bilateral optic nerve section, a spinal cord interruption at the cervical level, and a bilateral auditory nerve section could mimic the MEP pattern of brain death. MEPs can differentiate brain death from misleading factors, such as hypothermia, drugs, and metabolic disturbances, by the persistence of brainstem activities (waves from II to V in BAEPs and lemniscal P14 in median nerve SEPs).

Brain death diagnosis can be considered more difficult in infants than in children and adults, taking into account the immaturity of brainstem reactivity and EEG. The high proportion of anoxic encephalopathies in infants and the persistence of open fontanelles, which prevents transtentorial herniation, decrease the likelihood of a brain death occurrence in such comatose patients. BAEPs and VEPs are present in all premature infants older than 30 weeks. BAEPs are sensitive to pathologic conditions frequently encountered in infancy, such as anoxia (cochlea sensitivity) and hyperbilirubinemia (cochlea and brainstem sensitivity), that can give rise to null BAEPs. VEP alterations in anoxic infants are poorly documented. Cortical SEP components are inconstant, and their absence in normal term newborns is not pathological. After 6 months of age, the absence of cortical SEP components indicates a poor prognosis (death or severe neurologic sequelae). Consequently, MEPs should not be taken as a reliable brain death confirmatory test in these misleading conditions (anoxia, hyperbilirubinemia, and probably poisoning) in infants younger than 6 months old [42].

The interpretation of MEPs in poisoning cases should take into account some specifics. Concerning VEPs, it is important to keep in mind that the same factors that provoke electrocerebral silence (CNS depressant intoxications, hypothermia) can abolish the VEPs. A completely abolished VEP has the same meaning as electrocerebral silence. The lower sensitivity to environmental artifacts due to the averaging process is a significant advantage over EEG and makes the interpretation easier [42]. Owing to the high toxicity to retina and optic nerve of formic acid, the main toxic metabolite after biotransformation of methanol, VEP interpretation in

Fig. 4 Multimodality evoked potential pattern in a brain death patient. Multimodality evoked potentials were recorded from a 33-year-old man. At the time of recording, clinical examination was consistent with brain death diagnosis. Flash visual evoked potentials (VEPs) show only a retinal component (wave I) on the cortical channel and the

periocular recording. Median nerve somatosensory responses are represented only by peripheral (Erb) and spinal (N13) components, whereas brainstem and cortical components are bilaterally absent. Brainstem auditory evoked potentials (BAEPs) are limited to a cochlear nerve component (wave I) (From Ref. [21])

the case of methanol poisoning may not be reliable [44]. Early retinal dysfunction can be documented; it may or may not be followed by the development of optic neuropathy. In the case of disappearance of VEP activities in methanol poisoning, the preservation of BAEP and SEP components precludes the brain death diagnosis.

Hypothermia often is experienced in comatose patients secondary to poisoning or other causes. It has been shown that BAEPs also are less influenced by hypothermia and may help to rule out brain death diagnosis as long as the body temperature exceeds 20–22 °C [45]. From our experience in recording SEPs during profound hypothermia for surgical aorta repair, the lemniscal P14 of median nerve SEPs also is resistant to hypothermia and disappears only at temperatures less than 18 °C, whereas cortical SEP activities can be recorded at temperatures around 22 °C [46]. In most clinical situations, the hypothermia level is less marked and does not interfere with MEP interpretation.

There is a consensus among authors that SEPs and BAEPs can be considered relatively insensitive to CNS depressant drugs, and these evoked potentials are a good tool for examining brainstem function when these drugs are present [47–49]. Increased SEP latencies with increased central conduction time (as measured between cervical N13 and parietal N20) have been observed in amitriptyline, meprobamate, and nitrazepam overdose [50]. In the presence of CNS depressant drugs, BAEPs either are unchanged at therapeutic levels or are delayed at therapeutic or toxic levels. Amplitude or morphologic changes can occur with enflurane, cholinergic and serotonergic agents, phentolamine, and propranolol [51]. Mauguière and colleagues [52] showed deep reversible BAEP alterations consecutive to the association of barbiturates and lidocaine in one case. In our experience, barbiturate intoxication sufficient to provoke a clinical and EEG pattern of brain death is associated with well-preserved BAEPs and persistent lemniscal P14 in median nerve SEPs (Fig. 5). The MEP

Fig. 5 Electrophysiologic study in a 5-year-old epileptic girl under barbiturate. At the time of recording, blood level of thiopental was 53 $\mu\text{g/mL}$, and all cephalic reflexes were absent. The electroencephalogram was isoelectric during long periods. Median nerve somatosensory evoked

potentials (*SEPs*) show delayed but recognizable lemniscal (P14) and cortical (N20) activities. Brainstem auditory evoked potentials (*BAEPs*) are well preserved but slightly delayed (From Ref. [21])

pattern in brain death is clearly distinct from that observed in CNS depressant intoxication and allows clinicians to differentiate both states clearly. For most authors, evoked potentials might be included in brain death criteria even in clinically difficult conditions [47, 51, 53]. Drug intoxication cannot account for a complete MEP pattern of brain death if brain death is not really present. Subcortical (and even cortical) activities persist in high doses of CNS depressant drugs sufficient to give rise to a clinical and EEG pattern of brain death. The MEP pattern of brain death is encountered in other drug intoxications only when irreversible damage occurs at the brainstem and the cerebral cortex [54].

Organ Donation from Poisoned Donors

Organ donation after acute poisoning with evidence of brain death is a poorly documented topic [55–57]. The current shortage of grafts for organ transplantation should lead to consideration, in selected cases, of poisoned subjects as organ donors. Over the last 10 years, it seems that the use of drug-intoxicated patients in the USA as organ donors progressed significantly. In 2013, poisoned donors represented 6.8% of all organ donors (6.8% for kidney, 5.1% for pancreas, 7.1% for liver, 7.1% for heart, 5.7% for lungs) [58]. There was also a significant difference across all US states, with a peak of donation from poisoned patients at 10.4% in the regions of New York and Vermont.

The knowledge of both the target organ and mechanism of action of each toxin is important. To increase the donor pool, a close cooperation between ICU directors, clinical toxicologists, and transplantation surgeons is essential. A postal survey performed in 2002 in the UK revealed that most transplantation physicians and surgeons and ICU directors would consider those who die following acute drug intoxication and poisoning as potential organ donors [59]. With some specific toxins (methanol, carbon monoxide, cocaine), there was some concern regarding poison-induced organ damage. This concern is also present among

medical toxicologists, particularly for heart donation after cocaine or carbon monoxide exposure [60]. There is, however, an increasing evidence of good outcome when using poisoned patients as potential organ donors, with a large variety of toxins (tricyclic antidepressants, benzodiazepines, barbiturates, insulin, CO, methanol, cocaine, pesticides, snakebites, and other toxins) [61–74]. Published experience indicates that in selected cases, the organs from such donors function as well in recipients as organs from more conventional sources. Some centers report a favorable experience in this setting [63, 75].

A first step is to exclude the risk of toxin transmission to the recipient by careful analysis of the toxicologic data (undetectable or nontoxic blood toxin levels). A second step is to check that the systemic consequences of acute poisoning are fully controlled. The routine biologic data are extremely helpful in excluding organ dysfunction (nonelevation of cardiac, hepatic, and pancreatic enzymes and normal serum creatinine). Morphologic analysis also is essential but is often possible only at organ harvest when biopsy also can exclude gross organ injury.

Heart Donation

Heart donation from poisoned donors is poorly studied [75]. Similar to the brain, the heart is extremely sensitive to hypoxic or ischemic injury. Some toxins may preclude donation, such as tricyclic antidepressants, dextropropoxyphene, cocaine, and ethylene glycol. Tricyclic antidepressants may accumulate in heart tissue [76]. Ultrastructural changes have been noted in the myocardium of patients who died from acute ethylene glycol and cocaine overdose [77, 78]. Cocaine interferes with cardiac biochemical functions, leading to oxidative stress, and with cellular calcium flux regulation [79]. Clear evidence of recovery from these toxicities must be shown. The impact of current or previous use of cocaine in cardiac donors on the overall recipient survival and development of coronary artery disease in the recipient was studied retrospectively. On a total cohort of 7937 heart recipients, 11.7%

of individuals received a heart from a donor with a history of cocaine use [80]. The overall mortality at 5 years and the development of coronary artery disease at 5 years were not significantly different according to the nonuse, previous use, or recent use of cocaine. Heart donation after CO intoxication is still a matter of debate because fatal outcomes have been published [65, 81–87]. Reversible cardiac dysfunction may be observed after CO exposure, prompting the hypothesis of myocardial stunning [88]. Ultrastructural myocardial changes, after acute CO exposure, also have been debated. Different factors may be involved in CO cardiotoxicity, such as individual susceptibility, duration of exposure, and type of exposure (e.g., smoke inhalation). In a systematic review of the published literature on heart donation after fatal carbon monoxide poisoning, 42 carbon monoxide-related donor deaths were identified, with a follow-up extending up to 7 years for individual organs. There was no difference in the mean peak carboxyhemoglobin concentration in donors between organs that survived and those that did not. The survival was obviously lower for heart and lungs in comparison with kidney, pancreas, and liver. However, the outcome of heart (and lung) transplants from carbon monoxide-poisoned donors was comparable to that expected from organs donated from donors with other causes of death [82]. The influence of specific therapy (hyperbaric oxygen) has to be clarified. Experience with heart donation after methanol poisoning is still limited [71, 89–91]. Severe metabolic acidosis may contribute to myocardial dysfunction at the acute phase, but this has been poorly investigated in acute methanol poisoning. After the complete elimination of the toxin, heart donation should be possible provided that metabolic acidosis has been corrected and that inotropic drugs or vasopressors are not required.

Insulin and cyanide are good examples of functional toxins. Cyanide induces cellular hypoxia by inhibiting cytochrome oxidase. After cyanide exposure, successful cardiopulmonary resuscitation can be achieved by supportive therapy and antidote administration. Heart donation is possible after cyanide poisoning [92]. The main

problem is to prevent cyanide intoxication of the recipient. It seems safe to wait until the donor's serum cyanide concentration is less than 100 ug/dl (23 μ mol/L) and lactic metabolic acidosis has been corrected.

Fatal acetaminophen poisoning is particularly frequent in some countries. Heart donation seldom has been considered, however. According to the data in the literature, it is unlikely that acetaminophen is directly cardiotoxic [66].

What criteria could be applied to minimize risk in heart donation after fatal poisoning? A normal electrocardiogram, intact left ventricular function (estimated by echocardiography), good hemodynamics with minimal inotropic support, and normal or near-normal cardiac enzymes would seem essential [82]. With CO poisoning, additional requirements might include relatively short ischemia time, favorable donor-to-recipient weight ratio, and avoidance of recipients with high pulmonary vascular resistance. It also is wise to avoid donors with prolonged CO exposure or sustained cardiocirculatory arrest. [82, 87] The severity of organ damage cannot be predicted from the carboxyhemoglobin levels.

Finally, heart donation after poisoning with cardiotoxicants was exceptionally reported in a donor who received extracorporeal life support because of refractory cardiac arrest caused by a flecainide and betaxolol overdose [93]. This case illustrates the possible reversibility of some toxin-induced cardiac dysfunction, while the patient may suffer from irreversible brain damage.

Lung Donation

Lung transplantation from a poisoned donor has been described rarely [69, 94–96]. A few toxins directly affect the lung (e.g., paraquat or bleomycin) contraindicating organ donation. Cardiogenic or noncardiogenic pulmonary edema may complicate some toxic deaths, however. CO poisoning illustrates the different mechanisms of lung injury, but is not a contraindication for lung donation [82]. Caution should be exercised when lung donation is considered after smoke inhalation following fire hazard (associated chemical

injury) [95]. Concerning cocaine, there is a retrospective analysis on a thoracic transplant database showing no difference in the propensity of recipient survival based on donor cocaine status [94]. In other cases, standard lung donation criteria can be applied.

Liver Donation

The liver is a target organ for some toxins (e.g., acetaminophen and some mushrooms) to the extent that liver transplantation is a successful therapy in the most severe cases.

Liver donation is possible in selected cases, and successful liver allografts have been reported after poisoning with benzodiazepines, methaqualone, barbiturates, cyclic antidepressants, insulin, CO, cyanide, methanol, cocaine, pesticides, and lead [61, 63, 72–74, 82, 90, 91]. Detectable alcohol concentrations are common in the blood of potential organ donors after motor vehicle accidents, intracranial hemorrhage, head injury, aspiration, and drug overdose; they are not a contraindication per se to liver harvesting. Many toxins might be expected to accumulate in the liver (e.g., tricyclic antidepressants); in practice, this has rarely proved the case. Risk can be minimized by a careful toxicokinetic analysis. The decision to harvest the liver should be guided mainly by donor history (chronic ethanol or drug abuse), liver function tests, serology, and liver morphology and biopsy at harvest.

Kidney Donation

The kidneys are relatively resistant to many hypoxic, ischemic, or toxic insults. Acute tubular necrosis, usually secondary to nontraumatic rhabdomyolysis, may occur in this setting but is generally reversible. The kidney is a target organ of acute ethylene glycol poisoning. Nevertheless, kidney transplantation has been performed with success after exposure to this substance, but this cannot be recommended routinely. There is experimental evidence that oxalate crystal deposition may lead to an inflammatory response with

permanent epithelial cell injury, and some patients who survived acute ethylene glycol poisoning have developed chronic renal failure [97, 98]. Clear evidence of recovery from the injury must be shown. In other instances, there is extensive experience with kidney grafts from poisoned donors, and the results are similar to those in the nonpoisoned donor population. There is, for example, an important published experience of successful kidney transplantation from methanol-poisoned donors [70, 71, 90, 91, 99]. The kidneys can be transplanted safely after fatal acetaminophen poisoning, even in the presence of acute tubular necrosis, a possible but rare complication of acetaminophen poisoning that probably could not be prevented by *N*-acetylcysteine administration [100]. Kidney donation may be considered safely after acute poisoning by most toxins that are not directly nephrotoxic. Renal function laboratory tests and pretransplant biopsy are mandatory.

Pancreas Donation

Pancreas transplantation from poisoned donors has been described rarely. Alcohol abuse is associated with acute and chronic pancreatitis. Several studies of the acute effects of ethanol administration have shown that the liver is affected significantly more often than the pancreas; no correlation is found between blood ethanol and serum amylase or lipase levels. Similar to ethanol, methanol is a possible cause of pancreatitis [101]. Pancreas injury may be exacerbated further by the ethanol therapy used as an antidote to methanol intoxication. The decision to harvest the pancreas should be based on laboratory indicators and organ morphology at surgery.

Organ Donation from Non-Heart-Beating Poisoned Donors

Donation after circulatory death (DCD) describes the retrieval of organs for the purposes of transplantation that follows death confirmed using

circulatory criteria [102]. The practice of DCD is not accepted in all parts of the world due to ethical concerns around the interface of end-of-life care and organ donation. Donors dying from acute poisoning may belong to category II (unsuccessful resuscitation) or category III (anticipated cardiac arrest, treatment withdrawal) of Maas-tricht. The published experience on DCD reveals that most of the donors suffered from irreversible brain damage, either after intracranial hemorrhage or after severe brain anoxia. Currently, there is no direct description of donation from poisoned patients after circulatory death, with the exception of two cases of kidney donation from paracetamol-poisoned donors who died after a decision of treatment withdrawal [103]. It is, however, conceivable that patients with severe and irreversible brain anoxia due to poison-induced cardiac arrest or to oxygen deprivation (e.g., following carbon monoxide exposure) could increase the pool of donors after circulatory death.

Conclusion

In-hospital death, particularly brain death, is a rare complication of acute poisoning compared with out-of-hospital deaths from a toxic origin. The diagnosis of brain death relies not only on the clinical examination but also on confirmatory tests, especially in poisoning cases. Among them, transcranial Doppler, brain scintigraphy, cerebral angiography, and overall MEPs are less susceptible to the influence of drugs or metabolic disorders than is the EEG. Analysis of the more recent literature shows successful organ transplantations with grafts obtained from donors poisoned by various substances. Experience indicates that in selected cases, the organs from poisoned donors function in recipients as well as organs from more conventional sources. Physicians should be guided by the accurate knowledge of the target organs of poisoning, the analysis of the toxicokinetic data, and the results of laboratory investigations, functional tests, and morphologic studies before harvesting the organs.

While several large-scaled multicenter studies have changed the approach to the diagnosis and treatment of hypotension and shock in septic patients in recent years, the evidence base for the appropriate management of circulatory failure in poisoned patients is much more precarious. Toxicological research is often limited to case reports, small case series, or animal studies and most clinical recommendations or treatment guidelines are based on expert consensus or even personal experience rather than on criteria of evidence-based medicine [1]. Additionally, there may be a significant reporting bias from positive cases responding to different treatments, including extraordinary resuscitation measures. However, given the infrequency of many of these poisoning events, the likelihood of confirmatory randomized controlled trials to prove effectiveness will be low [2].

Most data regarding hemodynamics in critically ill patients are thus derived from nontoxicological populations, and it is often unclear if this evidence can uncritically be transferred to poisoned patients.

Current recommendations for the protocolized resuscitation of patients with sepsis-induced hypotension and shock suggest targeting a mean arterial pressure (MAP) of at least 65 mmHg, a central venous pressure (CVP) of 8–12 mmHg, a central venous oxygen saturation ($ScvO_2$) or mixed venous oxygen saturation (SvO_2) above 70% or 65%, respectively, and a urine output of at least 0.5 mL/kg per hour (1C) during the first

6 h of resuscitation [3, 4]. Additionally, normalizing lactate in patients with elevated lactate levels as a marker of tissue hypoperfusion has been suggested (2C) [4].

In contrast to the early-goal-directed therapy (EGDT) introduced by Rivers and colleagues in 2001 for the treatment of patients with septic shock [5], which has been both criticized and adopted during recent years [6, 7], a clear protocol-derived approach for poisoned patients with shock is still lacking.

In this chapter, pathophysiological aspects of hypotension and shock in poisoned patients will be discussed followed by discussion of appropriate diagnosis, and general and more invasive treatment options. Evidence of the proposed treatment modalities – if any – will be briefly discussed on the basis of the available literature. Detailed poison-specific management (e.g., antidotal therapy) is beyond the scope of this section but will be discussed in respective chapters of this textbook.

Epidemiology

Adverse cardiovascular events in poisoned patients are responsible for significant morbidity and mortality. Poisoning with cardiovascular drugs were involved in not more than about 4% of the 2.7 million reported overdoses in the USA in 2011, but accounted for about 11% of all reported drug fatalities [8]. While cardiac arrest and life-threatening hemodynamic instability are rather infrequent events of deliberate or accidental drug overdose, poisoning is the leading cause of nontraumatic death in patients under the age of 45 [9].

Although clear epidemiological data regarding cardiovascular complications in the course of poisoning are lacking, they account for significant morbidity and mortality in these patients. Drug-related adverse cardiovascular events occur with many drugs and mechanisms are diverse, depending on the underlying agent. The most common include dysrhythmias (e.g., ventricular tachycardia, ventricular fibrillation, torsade de pointes), hypotension and circulatory failure, myocardial injury (evaluated with cardiac

biomarkers and the ECG), or cardiac arrest [10]. The incidence of adverse cardiovascular effects in hospitalized poisoned patients is reported to be as high as about 17% [11].

Poisoning with membrane stabilizing agents (i.e., antiarrhythmic drugs, certain beta-blockers, cyclic antidepressants, selective serotonin reuptake inhibitors, antiepileptics, antimalarial agents, and dopamine and norepinephrine uptake inhibitors) and calcium channel blockers are responsible for the majority of cardiovascular deaths [12]. According to reports of the American Association of Poison Control Centers, calcium channel blockers and beta-blockers account for approximately 40% of cardiovascular drug poisoning but represent more than 65% of deaths from cardiovascular medications [13].

Interference with cellular physiology, metabolism, or receptor blockade in these poisonings frequently result in diminished effectiveness of standard advanced cardiac life support (ACLS) protocols, so antidotes or alternatives such as calcium, glucagon, high dose of beta-receptor agonists, insulin/glucose, or intravenous lipid emulsion therapy may be necessary [1]. Patients suffering from ventricular fibrillation or pulseless electrical activity should immediately undergo cardioversion or defibrillation. A nonexhaustive list of agents causing bradycardia or tachycardia in the course of poisoning is shown in Table 1.

Definition of Hypotension and Shock

The term shock in the critically ill (including poisoned) patient is defined by a significant reduction of systemic tissue perfusion, which results in a decreased delivery of oxygen and substrates to tissues. This mismatch between oxygen consumption and delivery leads to cellular hypoxia and consequently to the disruption of essential biochemical processes at the cellular level and can progress to a systemic reaction [14]. At the cellular level, ion-pump dysfunction, membrane leakage, intracellular edema, and acid–base dysregulation may occur and progress to systemic alterations in the serum pH and endothelial dysfunction – triggering inflammatory or anti-inflammatory cascades.

Table 1 Frequent agents that may cause hemodynamic relevant bradycardia or tachycardia, ultimately leading to severe shock or (functional) cardiac arrest

Agents that may lead to bradycardia	Agents that may lead to tachycardia
Beta-receptor blockers	Sodium channel blockers such as tricyclic antidepressants, type I antiarrhythmics, local anesthetics, chloroquine, quinine
Calcium channel blockers	Other pharmaceuticals (e.g., theophylline)
Alpha ₂ -receptor agonists (e.g., clonidine, dexmedetomidine)	Drugs of abuse (e.g., amphetamines, cocaine)
Cardioactive glycosides (e.g., digoxin, fox glove, yellow oleander)	Cardioactive glycosides (e.g., digoxin, fox glove, yellow oleander)
Cholinergic agents (e.g., organophosphate compounds, carbamates)	Natural toxins (e.g., aconitine, night-shadow plants)
Potassium channel blockers (type III antiarrhythmics) (e.g., sotalol, amiodarone)	Potassium channel blockers (type III antiarrhythmics) (e.g., sotalol, amiodarone)
	Noradrenaline reuptake inhibitors (e.g., venlafaxine)

Sequential cell death with end-organ damage, even progressing to multi-organ failure, may then ultimately lead to death.

Before hypotension or even shock become clinically obvious, inadequate oxygen delivery with increased serum lactate may occur and is frequently called “cryptic shock” with normal blood pressure but hypoperfusion at the tissue level.

Hypotension can be defined as absolute (e.g., systolic blood pressure <90 mmHg) or relative (e.g., drop in systolic blood pressure >40 mmHg). The latter may partly explain why patients may be in shock despite high or normal blood pressure levels. Focusing mainly on traditional resuscitation endpoints such as blood pressure (and cardiac output) carries a high risk of overemphasizing systemic hemodynamics at the cost of tissue perfusion [15]. Focusing mainly on macrocirculatory parameters (such as the mean arterial pressure) additionally implies a high risk of overusing

vasopressors, which in turn may further aggravate tissue hypoperfusion.

For early diagnosis and adequate treatment, it is therefore of paramount importance to realize that shock is defined as an imbalance between oxygen (and substrate) delivery and oxygen consumption. The patient can therefore be in shock irrespective of the level of blood pressure, which can be low, normal, or even elevated. Several studies have revealed that, within the autoregulatory limits of the heart and brain, arterial blood pressure poorly correlates with tissue perfusion in critically ill patients [15, 16].

Pathophysiology

Mechanisms of hypotension and shock in poisoned patients are diverse and can be a combination of cardiac, central, and peripheral mechanisms. Systemic tissue perfusion and the maintenance of blood pressure are determined by adequate cardiac output (CO) in combination with appropriate systemic vascular resistance (SVR). CO may be reduced due to toxin-induced myocardial depression, arrhythmia (abnormal impulse formation, conduction disorders, or triggered rhythms), and relative (venous pooling) or absolute hypovolemia (true fluid loss or third-spacing). The CO itself is the product of heart rate and stroke volume, the latter being related to preload, myocardial contractility, and afterload. SVR may be reduced due to drug-induced vascular relaxation, central depression of central vasomotor tone or peripheral adrenergic receptor blockade, or a combination of each. SVR is dependent on blood vessel diameter, length, and viscosity of the blood [17].

Hypotension and/or shock are a consequence of a reduction in CO, SVR, or both; however, even an elevation of the one may be seen when the other is disproportionately low. Three types of shock are usually distinguished [18]:

- *True hypovolemic* (e.g., severe hemorrhage, third-spacing) is usually not seen primarily in the setting of poisoned patients,
- *Cardiogenic* which can be myopathic, arrhythmic, mechanical, or extracardiac obstructive

Table 2 Different types of shock with corresponding hemodynamic variables

Clinical classification	Preload (PCWP)	Cardiac output (CO)	Afterload (SVR)	Tissue perfusion (S_{cvO_2})
Hypovolemic shock	Decreased	Decreased	Increased	Decreased
Cardiogenic shock	Increased	Decreased	Increased	Decreased
Distributive shock	Decreased or normal	Increased	Decreased	Increased

PCWP pulmonary capillary wedge pressure [normal: 9 ± 4 mmHg], *CO* cardiac output varies with body size and is the product of stroke volume \times heart rate [normal: 4–8 L/min], *SVR* systemic vascular resistance, determined by vessel diameter and distensibility (compliance). It is calculated by: $SVR = (MAP - CVP) \times 80/CO$ with MAP is mean arterial pressure [in mmHg] and *CVP* = central venous pressure [in cm H₂O], usually measured in the superior vena cava [900–1500 dyn \times s/cm⁵]; S_{cvO_2} , Central venous oxygen saturation [normal: 72%], usually measured in the superior vena cava

(e.g., pulmonary embolism, cardiac tamponade, or tension pneumothorax)

- *Distributive* (e.g., septic, toxic, anaphylactic, endocrine).

Measurement of CO, SVR, and eventually the pulmonary capillary wedge pressure (PCWP) can assist in differentiating these shock types. The mixed venous oxygen saturation (S_vO_2) is a clinical parameter of reduced tissue perfusion.

Combined shock is a mixture of these three different types of shock, coexisting in one patient (e.g., distributive and cardiogenic shock in a patient with calcium channel blocker overdose).

Hypovolemic shock is a result of decreased preload due to intravascular loss of fluid volume. PCWP (a parameter for preload) is reduced, CO (a parameter for pump function and myocardial contractility) is reduced, and the SVR (a parameter for the myocardial afterload) is compensatory elevated. Tissue perfusion is reduced.

In *cardiogenic shock*, CO is decreased and both the SVR and the PCWP are compensatory increased and tissue perfusion is reduced.

Finally, in *distributive shock*, CO is increased, PCWP may be normal or reduced, and SVR is diminished, resulting in an increased tissue perfusion. Table 2 gives an overview of several quantitative hemodynamic variables and their change according to the type of shock.

A more conceptual model of poison-induced shock with its differential diagnosis and important treatment considerations is summarized in Fig. 1.

Development of hypotension and shock usually is a physiological continuum starting with preshock

(“warm shock,” clinically often compensated due to adaptive physiological mechanisms), manifest shock (compensatory mechanisms start to fail and symptoms of organ failure may appear), and the stage of manifest end-organ dysfunction. An overview of different shock types with echocardiography findings is shown in Table 3.

Diagnostic Approach

Any patient with suspected cardiovascular poisoning should be immediately evaluated for potential hemodynamic compromise. Minimal requirements are a continuous cardiac monitoring, including pulse oximetry, noninvasive blood pressure measurement, and a 12-lead ECG performed to evaluate for cardiac ischemia, arrhythmia, and the potential of QRS-widening or QT interval prolongation [10].

Medical history often cannot be provided in patients in profound shock and must instead be obtained from relatives or medical records available. The physical examination should be straightforward and directed toward uncovering the type, severity, and cause of hypotension or shock. Usually, patients in shock present universal (cardinal) findings and more specific findings that may suggest a particular type of shock.

Cardinal findings in patients with manifest shock and/or end-organ dysfunction include hypotension, abnormal mental status (e.g., as a sign of cerebral hypoperfusion), oliguria (as a sign of intravascular volume loss and/or shunting of renal blood flow), metabolic acidosis (often with elevated serum lactate due to both decreased

Fig. 1 Flowchart of pathophysiology and treatment options of different types of toxic shock. BB beta-receptor blockers, CCB calcium channel blockers, LA local anesthetics

lactate clearance and/or increased production due to anaerobic metabolism in hypoxemic tissues), and in some patients cool and clammy skin (not seen in hyperdynamic states of shock) [17]. Cardiogenic pulmonary edema may complicate the clinical picture and is typically characterized by increased PCWP >20 mmHg. Evaluation of skin hypoperfusion – the largest organ of the body – can indicate even early stages of hypotension and shock. The term skin “mottling” describes a red-lilaceous discoloration of the skin due to reduction of blood flow in small skin vessels. It involves vessels with a high density of noradrenergic receptors, such as the knee [19]. Associated with decreased urinary output and altered consciousness, mottling over the knee is a well-known clinical sign of circulatory shock [18]. Two recent small sample studies reported an incidence of mottling between 46% and 70% in patients admitted for septic shock, and this was associated with increased mortality at day 14

[20, 21]. In a much larger recent prospective study on 791 critically ill patients, the overall incidence of skin mottling was 29%, and it was 49% in a subset of septic shock patients. The independently associated in-ICU mortality was significantly different at 8% in patients without mottling, 30% in patients with a short mottling, and 40% in patients with persistent skin mottling [22]. Therefore, assessment of mottling may be a simple and reliable parameter allowing continuously identifying patients with impaired peripheral perfusion and increased mortality. Importantly, as with other parameters of impaired peripheral perfusion (e.g., prolonged capillary refill, high skin temperature gradient, or hyperlactatemia), the occurrence of mottling may, however, be seen also in patients without the need of vasopressors or a MAP greater than 65 mmHg [22, 23]. Several parameters reflecting tissue parameters and clinically targeted endpoints are summarized in Table 4.

Table 3 Different types of shock and typically echocardiographic findings

Type of shock	Cardiac output	Echocardiography
Hypovolemic shock	Low (CVP low)	Small cardiac chambers Contractility normal or high
Distributive shock	Normal or high	Normal cardiac chambers Preserved (normal) contractility
Cardiogenic shock	Low (CVP high)	Large cardiac ventricles Impaired contractility
<i>Obstructive shock^a</i>	<i>Low (CVP high)</i>	<i>Pulmonary embolism/ pneumothorax Dilated right ventricle, small left ventricle Pericardial tamponade Pericardial effusion, small right and left ventricle, dilated inferior vena cava</i>

CVP central venous pressure

^aFor a complete differential diagnostic approach, although this type of shock is usually not seen in poison-induced shock

In the toxicological setting, the appearance of specific toxidromes and/or analytical confirmation of toxins may be helpful in the diagnosis of shock, but these should not delay early and aggressive treatment of hypotension or shock. It is also important to note that analytical confirmation of toxins is not universally present or available, and even when they are available there will often be a significant delay in obtaining results. In every case, physical findings are neither sensitive nor specific for identifying the cause of shock.

Whenever possible, focused echocardiography should be performed as soon as possible in any patient presenting with shock. Echocardiography should include assessment for pericardial effusion, measurement of left and right ventricular size and function, respiratory variations in the vena cava, and measurement of stroke volume [18, 24]. See also Table 3 for echocardiography signs, differentiating types of shock.

Laboratory tests should be performed early in the evaluation of patients with shock including basic chemistry (sodium, potassium, chloride, bicarbonate, blood urea nitrogen, creatinine,

Table 4 Parameters for tissue perfusion and suggested endpoints (Adopted from [15])

Class	Parameter	Endpoint
Peripheral perfusion	Tissue oxygen saturation Skin mottling Peripheral perfusion index Capillary refilling	≥70% Absence ≥1.4 ≤4.5 s
Venous oxygen saturation	Central (S _{CV} O ₂) Mixed (S _V O ₂)	≥65–70% ≥60–65%
Arterial lactate	Absolute Lactate clearance	≤2 mmol/L ≥20% decrease/2 h
Urine output	Quantitative	≥0.5 mL/kg/h

Peripheral perfusion index is derived from pulse oximetry signal and defined as the ratio between the pulsatile component of the light reaching the light-sensitive cell of the pulse oximetry probe; S_{CV}O₂ central venous oxygen saturation, S_VO₂ mixed venous oxygen saturation

liver function tests, lipase), coagulation studies (international normalized ratio, partial thromboplastin time), cardiac enzymes, arterial blood gas, toxicology screen, and lactate level. A complete blood count including a hemogram may differentially indicate a septic origin of shock. Venous whole blood lactate correlates with arterial lactate and is appropriate to screen for shock.

Catecholamines are well known to increase arterial lactate concentrations either by exaggerated stimulation of aerobic glycolysis [25] or induction of tissue hypoperfusion by inappropriate vasoconstriction [26, 27]. Although clearance of lactate is more delayed than the increase of MAP or CO, blood lactate level should decrease within hours and may indicate if therapy is effective [18]. Targeting a decrease of 20% in blood lactate within 2 h in patients with shock and an initial lactate level >3 mmol/L has been shown to be associated with reduced in-hospital mortality [28].

Hemodynamic Variables Assessing Severity of Hypotension and Shock

Since circulatory shock represents an imbalance between oxygen supply and requirement, maintenance of adequate oxygen delivery to the tissue is

essential and principally determined by CO. Absolute measures of CO are less important than monitoring trends in response to different treatment strategies and to target a predefined CO is not advisable since the CO needed will significantly vary, even in the same patient over time [18].

In a retrospective cohort study of 119 patients with cardiogenic shock (as a result of an acute coronary syndrome), cardiac index (CI) and cardiac power index (CPI) during the first 24 h after admission to intensive care unit were the most important hemodynamic variables separately associated with 28-day mortality. A CI of 3 L/min/m² and a CPI of 0.8 W/m² were most predictive of 28-day mortality [29]. The relative risk of death at day 28 substantially increased when CI dropped below 2 L/min/m² and CPI dropped below 0.4 W/m². Comparable cut-off values have been reported in other studies [30, 31]. Interestingly, no hemodynamic variable was associated with arterial lactate level however epinephrine and norepinephrine doses were [29]. Even though none of the hemodynamic variables commonly measured (e.g., MAP, CVP, SVR) were associated with outcome in this analysis, it is important to note that patients with cardiac shock due to acute coronary syndrome and patients with other causes of shock (i.e., vasodilatory shock, combination of central and peripheral circulatory failure due to poisoning, etc.) may differ substantially from a pathophysiological perspective.

Hemodynamic measurement can be helpful in determining the type of shock (see above and additionally in Table 2) and can also be used to titrate vasopressor therapy, assess hemodynamic effects of changes of respiratory settings, and guide fluid resuscitation. Hemodynamic optimization using, e.g., goal directed fluid therapy (GDFT) has been correlated with improved outcomes, at least in surgical patients [32]. The evidence supporting GDFT is sufficiently strong that national recommendations by the UK, France, and other European countries have embraced this approach [33].

Pulmonary artery catheterization (PAC) can obtain CO, PCWP, and SVR. However, it is

invasive, requires a certain level of operator skill and experience, and has potential hazardous side effects such as hemorrhage, rupture of pulmonary vessels, valvular erosions, dysrhythmia, line sepsis, and endocarditis [34]. Furthermore, it has never been shown to improve patient-important outcome parameters [35]. Other less invasive but accurate types of hemodynamic measurement are available and have more and more replaced PAC – which is now generally reserved for the perioperative monitoring of cardiac surgery patients. The less invasive PiCCO-system (PiCCO® Pulsion, Germany) generates CO, SVR, extra vascular lung water, and intrathoracic blood volume (a cardiac preload parameter). It can further add several mathematically derived hemodynamic variables by the means of changes in transpulmonary thermodilution. It needs an arterial catheter with a thermistor on the tip and can typically be placed in either the radial or femoral artery using Seldinger's technique. It can detect changes in temperature (dependent on hemodynamic properties) after injection of a bolus of ice-cold saline (typically 10–20 mL) via the central venous line. This system has been shown to accurately, reliably, and precisely predict hemodynamic variables, as compared to the “gold standard” PAC [36, 37].

While advanced hemodynamic monitoring has become more and more clinically routine in the assessment of hypotension, shock, or sepsis, its use in poisoned patients seems largely underrepresented, and its impact on patient outcome has never been evaluated. As a result, literature regarding this diagnostic approach in the poisoned patient is extremely scarce and limited to single case reports [34]. Consequently, no evidence about its accuracy or usefulness in this setting can be derived.

Furthermore, there is no evidence supporting the role of CVP (targeting between 8 and 12 mmHg) or S_{CV}O₂ (>70%) as an endpoint for fluid therapy [6, 38]. Evidence indicates that CVP does not correlate with volume status but is influenced by factors such as right ventricular function, intrathoracic pressure, and venous compliance, and protocols using the CVP as a guide to fluid therapy may result in over-resuscitation in a substantial number of patients [39, 40].

Adherence to the bundle of parameters as suggested by Rivers et al. [5], such as CVP above 8 mmHg or above 12 mmHg during mechanical ventilation, MAP >65 mmHg, diuresis >0.5 mL/kg/h, $S_{cv}O_2$ > 70%, and lactate <1.5 mmol/L or a decline in lactate levels have been repeatedly criticized in the recent years [41–43]. This holds true particularly for the CVP, the arbitrarily chosen MAP >65 mmHg, but also the $S_{cv}O_2$. The recently published ARISE study enrolling 1600 patients with early septic shock, which were assigned either to an EGDT-approach or an usual-care group, did not find a significant difference in survival time, in-hospital mortality, duration of organ support, or length of hospital stay. Moreover, the EGDT-approach did not reduce all-cause mortality at 90 days, critically questioning the value of such a protocol driven approach [6]. Volume and hemodynamic management should therefore no longer be based on unproven or imprecise surrogate parameters but should consider the actual hemodynamic situation of the individual patient. Evaluation of the cardiac pump function could be obtained easily and rapidly using echocardiography. Filling of the right ventricle and the vena cava can reliably be measured with little training. Surprisingly, the recent surviving sepsis campaign does not consider any methods of bedside hemodynamic evaluation, such as ultrasonography, in their guidelines [4]. The recently closed but not yet published ProMISe study investigating EGDT compared to standard care in targeted 1260 patients in 56 hospitals in the UK will hopefully add some new evidence on the appropriate diagnostic approach for diagnosis of shock. Needless to say, however, this evidence will relate to septic shock patients but not critically ill poisoned patients.

Management

Early and adequate hemodynamic support of patients in shock is crucial to prevent worsening of organ dysfunction and failure. The initial management of shock should be problem oriented and the initial targets are therefore the same,

regardless of the cause, although definitive treatments to reach the goals may differ [18]. The VIP rule is a simple mnemonic to describe essential components of resuscitation and includes [44]: ventilate (administration of oxygen), infuse (fluid resuscitation), and pump (administer vasoactive agents and/or inotropes).

Beyond specific toxicological treatment options, there are of course some important principal supportive and even more aggressive treatment modalities for patients with hypotension and shock, which will be discussed hereunder and are also depicted in Fig. 1.

Antidotal Therapy

Several agent specific antidotes along with the use of glucagon as an agonist of the class B G-protein coupled family of receptors with absence of peripheral vasodilatory effects (e.g., in beta-blocker poisoning) [45], high-dose insulin euglycemia (HIE) therapy (e.g., in beta-blocker or calcium channel blocker overdose, but also other types of shock), and rescue therapy with intravenous lipid emulsion (ILE) (e.g., local anesthetics, other lipophilic drugs) might be beneficial in the management of poisoning leading to severe hypotension or shock, although the clinical effectiveness of these antidotes is mostly based on low-level evidence. These specific treatment modalities, along with the suggested dosing, are discussed in the respective chapters of this textbook.

There are also more specific treatment modalities for poisonings with cardiovascular agents (e.g., Fab-antidotal therapy for digitalis poisoning; enhanced elimination procedures, including single-pass albumin dialysis, the molecular adsorbents recirculating system (MARSTM) technique, or plasma exchange therapy), which are discussed separately within the respective chapters of this textbook. Although the latter extracorporeal elimination techniques may have a role in very special settings of highly protein-bound drug-overdoses (where conventional hemodialysis fails) [46, 47], it is needless to say that most of these techniques require a minimum degree of hemodynamic

stability (i.e., sufficiently high CO) to be applicable – a prerequisite that essentially limits their use in patients with poison-induced severe hypotension, shock, or even cardiac arrest.

Fluid Resuscitation

Regarding cardiovascular stabilization in case of arterial hypotension or tissue hypoperfusion, early aggressive fluid resuscitation has been recommended, at least for the management of patients with severe sepsis and septic shock [3]. In an update of these international guidelines in 2012, initial fluid resuscitation with crystalloids (Level of Evidence [LoE] 1B) achieving a minimum of 30 mL/kg and consideration of the addition of albumin in patients who continue to require substantial amounts of crystalloids to maintain adequate MAP (LoE 2C) with the avoidance of hydroxyethyl starch formulations (1C) was recommended, based on the results of the VISEP [48], CRYSTMAS [49], 6S [50], and CHEST [51] trials. The latter studies are, however, questioned by the latest CRISTAL trial, which investigated the effects of fluid resuscitation with colloid versus crystalloid on mortality in 2857 mixed critically ill patients (sepsis, trauma, or hypovolemic shock without sepsis or trauma) presenting with shock. In this study, the use of colloid versus crystalloid did not result in a significant difference in 28-day mortality, and 90-day mortality was lower among patients receiving colloid rather than crystalloid, although this finding was considered exploratory and requires further research before reaching conclusion about efficacy [52]. A detailed review of the choice of resuscitation fluids was provided recently [53].

As stated in the surviving sepsis campaign, more rapid administration and greater amounts of fluid may be needed in some patients (LoE 1C). Fluid challenge techniques should be continued as long as hemodynamic improvement based on either dynamic (e.g., change in pulse pressure, stroke volume variation) or static (e.g., arterial pressure, heart rate) variables is observed [4].

Adherence to and variation in recommendations of the surviving sepsis campaign, however,

considerably varies between European intensive care units, as a cross-sectional survey between 145 ICUs of 16 European countries undertaken in 2009 demonstrated [54]. Particularly, the choice of fluid for resuscitation and the choice of the first-line inotropic drug differed significantly between centers, although norepinephrine was clearly the preferred vasopressor drug and nearly 50% of the respondents claimed to use supplementary vasopressin when norepinephrine dose exceeded a predefined level. The most commonly claimed hemodynamic variables to guide shock resuscitation were MAP (87%), $S_{CV}O_2$ (65%), CVP (59%), S_vO_2 (42%), and CI (42%) [54].

Fluid resuscitation in hypotensive patients, with or without shock, is the mainstay of therapy with the goal of obtaining adequate preload, ventricular filling, and tissue perfusion. Pragmatic endpoints for fluid resuscitation, however, are difficult to define. In general, the objective is for CO to become preload-independent (i.e., on the plateau of the Frank-Starling curve), but this is clinically difficult to assess [18]. Variations in the beat-by-beat stroke volume measured with CO monitors or indirectly observed variations in the pulse-contour wave in mechanically ventilated patients may be signs of fluid responsiveness but have some limitations [55]. A passive leg-raising test is an appropriate alternative method but requires a rapid response device since the effect is transient [18, 56].

Aggressive fluid resuscitation should, however, be used judiciously in patients at risk of fluid overload or pulmonary compromise (e.g., pulmonary edema, ARDS [acute respiratory distress syndrome], pneumonia) and optimally be adjusted using accurate hemodynamic monitoring (e.g., thermodilution including pulse-contour wave analysis, e.g., PiCCO[®]), or bedside echocardiography evaluating myocardial pump function, cardiac filling pressures, and the vena cava. Measures using the PiCCO[®] technique have been shown to adequately target the amount of volume needed, and to prevent side effects resulting from fluid overload, especially in patients with ARDS [57, 58].

In contrast, in a recently published study, patients with septic shock and/or ARDS were

randomized to a treatment algorithm based on parameters derived from PiCCO[®] or to a CVP-based algorithm. PiCCO[®]-based fluid management did not improve outcome based on the 28-day mortality [59], although it was somewhat unfortunate that patients in the PiCCO[®]-group had significantly higher baseline SOFA and APACHE II scores, both of them clearly having impact on the mortality [60].

A recent systematic review and meta-analysis including 36 clinical studies with 1224 patients investigated targets of perioperative fluid therapy and their effects on postoperative outcome. Three specific targets were identified: a systolic or pulse pressure variation <10–12%, an increase in stroke volume <10%, and a corrected flow time of 0.35–0.4 s. in combination with an increase in stroke volume <10%. Targeting one of these goals resulted in fewer postoperative complications and a shorter length of intensive care unit/hospital length of stay, but postoperative mortality remained unaffected [61]. It is, however, still to be defined whether all of the above mentioned surrogates to guide fluid resuscitation might also be reliably applicable to the subgroup of poisoned patients suffering from severe hypotension or shock.

Should a Target MAP >65 mmHg Generally Be Maintained?

Tissue and microcirculatory perfusion are physiologically regulated by blood flow and not the absolute arterial blood pressure itself. Consequently, the ideal MAP target in patients with shock remains a matter of debate [62–64]. In a recently published multicenter trial in 776 patients with septic shock, 388 underwent resuscitation with a high-target MAP (80–85 mmHg) and were compared to 388 patients with a conventional low-target MAP (65–70 mmHg). This study did not show differences in mortality at either 28 or 90 days, or in the overall rate of serious adverse events, although patients in the higher MAP group had significantly more episodes of atrial fibrillation. Of note, in a subgroup

of patients with chronic arterial hypertension, a MAP of around 75–85 mmHg reduced the development of acute kidney injury [65]. In another very recent critical reappraisal of the literature, the authors concluded that a MAP of 65–75 mmHg is usually sufficient in patients with septic shock, but the time to achieve the target as well as the technique used to increase MAP needs further investigation [66].

In a post hoc analysis in 290 septic shock patients, MAP levels above 70 mmHg were not associated with 28-day mortality but higher catecholamine doses were significantly associated with adverse events, such as occurrence of acute circulatory failure, metabolic acidosis, renal failure, and thrombocytopenia [67].

The association between different arterial blood pressure values during the first 24 h after ICU admission, 28-day-mortality and organ function was evaluated in 274 septic patients. In this study, arterial blood pressure was associated with 28-day-mortality even when corrected for the impact of disease severity [68]. Currently, a MAP of 65–90 mmHg is a widely accepted and recommended blood pressure range for critically ill patients [69]. In the study of Dünser, there was no difference in the risk of death at 28 days between arterial blood pressure drops below MAP 65, 70, and 75 mmHg. However, a MAP of 60 mmHg during the first 24 h after ICU admission reflected a critical level as one or more episodes of MAP <60 mmHg increased the risk of death by 2.96 (CI 95%, 1.06–10.36; $p = 0.04$). The authors concluded that a MAP level equal or >60 mmHg may be as safe as higher MAP levels and may contribute to the use of lower doses of catecholamines, thereby reducing side effects and possibly increasing tissue perfusion [68].

Considering whether critical care physicians should strictly adhere to the recommendation to target a MAP above 65 mmHg and with regard to the published evidence to critically scrutinize these guidelines, a three-step approach of resuscitation endpoints based on growing evidence and physiological considerations was proposed recently [15]. Even though this algorithm has

Fig. 2 Stepwise approach to maintain sufficient organ (renal) perfusion, despite MAP <65 mmHg (Adopted from Ref. [15])

been suggested for septic shock patients only, it may be considered for poison-induced hypotension and shock as well (see Fig. 2).

1. In step one, a minimum individual and context-sensitive arterial blood pressure to preserve heart and brain perfusion should be targeted. A MAP between 45 and 50 mmHg rather than at least 65 mmHg is usually considered sufficient, respecting individual cardiac constellations, which may demand higher MAP values. Despite the fact that MAP does not accurately predict global tissue perfusion, it correlates well with coronary and cerebral blood flow.
2. In step two, tissue perfusion endpoints irrespective of MAP <65 mmHg (“permissive hypotension”) should be achieved considering: arterial lactate, peripheral perfusion, urine output, venous oxygen saturation (or a combination of these); see also [15].
3. In step three, markers of single-organ (mainly renal) perfusion should be targeted. Of all internal organs, the kidneys have the poorest capability to adjust to reductions in blood flow [70], therefore optimizing single-organ perfusion is in most patients equivalent to optimizing renal perfusion [15]. This can be achieved by increasing dose of norepinephrine (after

targeting step 1 and 2), critically weighing the potential risks of intensifying catecholamine therapy. This approach may be accompanied by ultrasonographic determination of the renal resistive index to optimally adjust vascular tone to improve kidney perfusion [71].

Vasopressors and Classical Inotropes

Adrenergic agonists have a rapid onset of action, high potency, and a short half-life, making them easy to dose, and they are therefore considered as first-line vasopressors. However, due to their potential harmful effects with myocardial ischemia, pure β -adrenergic agents – such as isoproterenol – should be limited to patients with severe bradycardia. On the other hand, the use of pure α -adrenergic agents – such as phenylephrine – is rarely indicated as they can decrease CO and impair tissue perfusion [18].

In their initial international surviving sepsis campaign, use of norepinephrine or dopamine as first-line vasopressor drugs or dobutamine as inotropic support has been recommended [3]. In the latest update, norepinephrine is still recommended as the first-choice vasopressor (0.1–2.0 $\mu\text{g/kg/min}$) to maintain a MAP

>65 mmHg (LoE 1B), adding epinephrine when an additional agent is needed to maintain adequate blood pressure. Vasopressin (0.03 U/min) can be added to norepinephrine to either raise MAP to target or to decrease norepinephrine dose, but it should not be used as the initial vasopressor (ungraded). Dopamine was recently associated with an increased mortality among patients with cardiogenic or septic shock and is no longer recommended in the surviving sepsis campaign, except for highly specific circumstances, e.g., patients with low risk of tachyarrhythmia and absolute or relative bradycardia (LoE 2C), and it should not be used for renal protection (LoE 1A) [4, 72, 73]. Dobutamine infusion (up to 20 µg/kg/min) administered or added to vasopressors in the presence of either myocardial dysfunction (e.g., elevated cardiac filling pressures and low CO) or ongoing signs of hypoperfusion (despite achieving adequate intravascular volume and adequate MAP) is recommended (LoE 1C). It was recommended not using a strategy of inotropic therapy to increase cardiac index to predetermined supra-normal levels (LoE 1B) [4]. Epinephrine, with predominantly β-adrenergic effects at lower doses and additional α-adrenergic effects at higher doses, did not show any beneficial effects over norepinephrine in septic shock patients and should reserve as a second-line agent for severe cases [4, 62].

It is unquestionable that catecholamines are highly effective to counteract cardiovascular instability, but they can be associated with numerous side effects, particularly at higher doses – with the most devastating negative effects on the heart [74]. For example, high doses of vasopressors (e.g., norepinephrine >0.5 µg/kg/min) in septic shock patients were associated with excessively high mortality [20]. Catecholamines have also repeatedly been associated with disease-related events on cardiac function ranging from tachycardia, ischemia to myocardial stunning, and apoptosis [74].

In a prospective observational study on 112 surgical intensive care unit patients with cardiovascular failure requiring catecholamine therapy, almost half of the patients (48.2%; 95% CI, 38.8–57.5%) developed 114 adverse cardiac events and these were related to both morbidity

and mortality. Specifically, the most frequent adverse events included new onset of tachyarrhythmia (49.1%), prolonged elevated heart rate (23.7%), and myocardial cell damage (17.5%), as reflected by increase in troponin T serum levels [75]. Both the extent and duration of catecholamine vasopressor therapy were independently associated with adverse cardiac events. Myocardial stunning, diastolic dysfunction, and increased ventricular afterload may all explain persistent reductions in systemic blood flow during treatment with (high doses of) vasopressors [76].

These negative effects might be reduced using a catecholamine-sparing treatment regimen whenever possible, including adequate fluid resuscitation or adding vasopressin, which has been shown to significantly reduce norepinephrine requirement without increasing the risk of serious adverse events in vasodilatory shock [77].

While there is no clear evidence to support the use of any vasopressor agent in poisoned patients with shock, both α-adrenergic vasoconstriction and β-adrenergic support of chronotropy and inotropy seems intuitive and should be the goal of therapy. For example, norepinephrine has been associated with improved outcomes in TCA-overdosed patients [78] and norepinephrine and epinephrine are recommended in current toxicological textbooks as the catecholamines of choice [79]. It should be noted, however, that there are some poisonings (e.g., overdoses with β-blockers/calcium channel blockers) where conventional or even high doses of α/β-agonists have proven to be less effective in the treatment. In these particular overdoses, alternative antidotal strategies may be required (e.g., high-dose insulin treatment, intravenous lipid emulsion, calcium salts) as discussed in more detail in chapters dealing with these specific poisonings [80, 81].

Use of high-dose vasopressor therapy in the management of drug-induced cardiovascular shock refractory to standard therapy has been discussed repeatedly. In the 1992 American Heart Association (AHA) guidelines, norepinephrine was recommended to be added if more than 20 µg/kg/min of dopamine was needed to maintain blood pressure. Epinephrine (2–10 µg/min)

was regarded as an alternative to be used in patients not in cardiac arrest (e.g., in symptomatic bradycardia), although it was not considered as a first-line agent. Norepinephrine was considered indicated in patients with severe hypotension (systolic blood pressure <70 mmHg) and a low systemic vascular resistance (SVR). Patients in refractory shock were deemed to require 8–30 $\mu\text{g}/\text{min}$ norepinephrine [82]. In the TOX-ACLS guideline from 2001 [83], a case report (LoE III) [84] and one animal study (LoE IIb) [85] supported the recommendation to use high-dose vasopressors in the management of drug-induced cardiovascular shock refractory to conventional therapy; these reports are discussed in more detail in the following paragraphs.

In the case report of Kalman et al., a 55-year-old man ingested 1200 mg atenolol together with 2880 mg slow-release verapamil. Vital signs at admission showed severe hypotension (systolic blood pressure 40–50 mmHg) and bradycardia (20/min). Treatment with atropine, prenalator, intravenous fluids, and calcium gluconate was ineffective, as was administration of dobutamine and isoprenaline. Only the combined infusion of epinephrine (up to 2.5 $\mu\text{g kg}^{-1} \text{min}^{-1}$), norepinephrine (up to 0.5 $\mu\text{g kg}^{-1} \text{min}^{-1}$), and dopamine (50 $\mu\text{g kg}^{-1} \text{min}^{-1}$) resulted in sustained cardiovascular stability and inotropes were discontinued 2 days after admission. No adverse events from the massive catecholamine infusion were reported, and the patient could be discharged at day 5 without sequelae [84].

In the study of Knudsen et al., the authors investigated different doses of epinephrine or norepinephrine (0.1, 0.5 or 5 $\text{mg kg}^{-1} \text{min}^{-1}$) in amitriptyline-intoxicated rats (0.625 $\text{mg kg}^{-1} \text{min}^{-1}$ amitriptyline by infusion throughout the experiment). Both epinephrine and norepinephrine appeared effective in reversing amitriptyline-induced cardiovascular shock, and they both significantly increased contractility, MAP, and heart rate, but epinephrine showed higher survival rates and had fewer arrhythmogenic properties compared to norepinephrine. The authors concluded that epinephrine may be the preferable inotrope for amitriptyline-induced cardiovascular shock [85].

In contrast, another good quality animal study (LoE IIb) in propranolol (30 $\text{mg kg}^{-1} \text{h}^{-1}$) intoxicated and spontaneously breathing rats did not show any beneficial effect on cardiovascular and respiratory variables or survival time, for the nonselective β -agonist isoprenaline (up to 50 $\mu\text{g kg}^{-1} \text{min}^{-1}$), the selective β_1 -agonist flerobuterol (up to 10 $\mu\text{g kg}^{-1} \text{min}^{-1}$), or for the β_2 -selective lipophilic agonist clenbuterol (up to 50 $\mu\text{g kg}^{-1} \text{min}^{-1}$) [86].

High-dose vasopressors may, however, induce ventricular dysrhythmias in hearts already prone to dysrhythmia and close cardiac monitoring (including central hemodynamic measurement of CO and SVR), careful selection of agents, and titration of doses is mandatory. Vasopressors should be rapidly titrated until shock is adequately treated or until recurrent ventricular dysrhythmias, signs of peripheral vasoconstriction, or an above-normal SVR is observed (LoE IIb) [83]. In patients with underlying or toxin-induced cardiac dysfunction, any vasopressor-mediated increase in SVR augments left ventricular afterload and may thus reduce CO, which in turn means no or little benefit for the tissue perfusion [87].

It is thus very difficult to draw any conclusive recommendation about the usefulness of high-dose vasopressors or inotrope agents in toxin-induced cardiovascular shock, as protocols, investigated toxins, doses, class, and route of administration of vasoactive agents have varied between different studies.

Besides traditionally used vasopressor agents, there are some newer vasopressors, namely, 4-aminopyridine (4-AP), indicating positive responses in single human case reports and murine studies of intractable shock and hypotension resulting from calcium channel blocker overdose [88–91]. 4-aminopyridine indirectly influences calcium channels as it selectively blocks the potassium channels K1 on the cytoplasmatic side of the cellular membrane, thereby depolarizing the cell and opening voltage-dependent calcium channels [91, 92]. Rodent and feline models have demonstrated hemodynamic improvements of verapamil poisoning with infusion doses of 1–2 mg/kg 4-AP [89, 93, 94]. Cardiac output and blood pressure

were improved by 4-AP alone and in combination with levosimendan in a rodent model of verapamil poisoning [88, 92].

Metaraminol (Aramine®), a catecholamine with predominant alpha-adrenergic receptor activity, was successfully administered in a significant amlodipine overdose (560 mg) who failed to clinically respond to conventional treatment, including fluid resuscitation, administration of calcium salts, glucagon, and norepinephrine/epinephrine [95]. Metaraminol at a concentration between 0.5 and 1.5 $\mu\text{g kg}^{-1} \text{min}^{-1}$ has potent peripheral vasoconstrictor activity with negligible effects on both myocardial function and cardiac output, thereby only minimally increasing myocardial oxygen demand [95, 96]. However, although widely used in Southeast Asia and Australasia, Metaraminol is infrequently used in Europe and the USA, and experience in drug-induced shock with this agent is very limited, so far.

Despite promising clinical effects of 4-AP and metaraminol in single cases or animal studies of calcium channel blocker overdose, further investigations are required to define whether these agents could enrich our armamentarium in the treatment of poison-induced shock.

Other Inotropes and Phosphodiesterase-III Inhibitors

The evidence for clinical meaningful benefits of newer inotropes in the treatment of severe hypotension or shock is weak. Data regarding the use of inotropes in poisoned patients are scarce and even in the specific cardiologic setting there are at present no robust or convincing data to support a distinct inotropic drug-based therapy as superior to reduce mortality in hemodynamic patients with cardiogenic shock or low CO as a complication of acute myocardial infarction – as stated in a recent comprehensive Cochrane Review [97].

Inotropes improve myocardial contractility and induce additional reduction of SVR for left ventricular afterload, thereby increasing cardiac output [98]. However, inotropes increase myocardial oxygen demand, induce cardiac arrhythmias, and may thus worsen heart function, especially in

the circumstances of myocardial infarction or cardiogenic shock [99]. In fact, clinical trials using classical inotropic agents (i.e., dobutamine, enoximone, or milrinone) suggest that both short-term treatment of acute heart failure without an essential requirement for inotropic support as well as long-term inotropic therapy in patients with severe chronic heart failure might increase arrhythmias and mortality [100, 101]. A retrospective analysis of 329 patients compared hemodynamic and clinical effects of milrinone (a PDE-III-inhibitor, also called inodilator) versus dobutamine. Despite more favorable hemodynamic effects in patients treated with milrinone, there was no statistically significant difference in in-hospital mortality between milrinone (7.8%) or dobutamine (10%) treated patients [102]. Although dobutamine led to more sinus tachycardia, both agents carried a significant risk of atrial and ventricular arrhythmias, probably related to increased intracellular calcium levels [103].

The use of vasodilators is furthermore often limited by hypotension and requires invasive hemodynamic monitoring to be administered safely. Moreover, in patients with severe hypotension or shock, even traditional inotropes (e.g., dobutamine or milrinone) may be poorly tolerated due to their vasodilatory effects. In these scenarios, peripherally acting agents (e.g., vasopressors) may be transiently required to increase blood pressure during the initiation of inotropic therapy [99]. In cases with potentially reversible insults (i.e., intoxication, acute myocardial infarction, and fulminant myocarditis), inotropes can serve as a bridge to a definitive therapy (e.g., revascularization) or recovery (e.g., falling levels of toxins).

Levosimendan

Levosimendan is a calcium sensitizer, enhancing myocyte sensitivity to calcium and thereby increasing force of contraction and improving CO. At higher doses, levosimendan also inhibits PDE-III, similar to other PDE-inhibitors such as milrinone. Finally, levosimendan has vasodilatory

properties through its action on adenosine triphosphate-sensitive potassium channels [99]. Levosimendan was found to have an additional distinct vasodilatory effect mediated by opening ATP-sensitive potassium channels (K_{ATP}) in vascular smooth muscle. A further postulated cardioprotective effect remains incompletely understood, but opening of mitochondrial K_{ATP} channels may play a crucial role [104]. The drug increases CO by 30–50% and decreases elevated filling pressures by a similar degree after a bolus dose of 6–12 $\mu\text{g/kg/min}$ followed by infusion of 0.2 $\mu\text{g/kg/min}$, as recommended by the manufacturer. According to a recent meta-analysis of randomized controlled studies (in nonpoisoned patients), the recommended dose range for levosimendan is 3–36 $\mu\text{g/kg}$ as intravenous bolus and 0.05–0.6 $\mu\text{g/kg/min}$ for continuous infusion [105].

Levosimendan as a vasodilator decreases both right and left ventricular preload and afterload. However, hypotension may limit or even lead to discontinuation of levosimendan, thus adequate fluid resuscitation along with low-dose vasopressors may be required in certain cases.

One key factor considered important in sepsis-induced (and probably toxin induced) myocardial depression is an alteration in calcium homeostasis within the cardiac myocyte secondary to circulating cytokines [106]. Other potentially beneficial effects include opening of K_{ATP} channels (resulting in improved tissue oxygenation and organ protection) along with anti-inflammatory properties of levosimendan and relaxation of vascular smooth muscle, which could lead to an improvement in perfusion, especially in hypoperfused areas such as the gastrointestinal tract [104, 107]. Levosimendan is, however, costly and has a half-life of several days, preventing timely dose adjustment in acute shock states which can limit its use in these circumstances [18].

In a small prospective, randomized open-label study comparing levosimendan and enoximone in refractory cardiogenic shock complicating acute myocardial infarction, survival rate at 30 days was significantly higher in the levosimendan-treated group (69% vs. 37%, $p = 0.023$); the latter

needed also a lower cumulative dose of catecholamines. However, only 32 patients were included in this study [108]. Effective use of levosimendan in Takotsubo cardiomyopathy has been also reported, and as a noncatecholamine inotrope, levosimendan may theoretically offer a rational treatment opportunity in this particular scenario [109].

Overall, although inotropes such as levosimendan in septic shock patients or patients with acute heart failure have been shown to improve cardiac parameters and despite promising single small studies, the proven evidence does not demonstrate improved overall survival [97, 110]. A currently recruiting randomized controlled trial (Levosimendan for the prevention of acute organ dysfunction in sepsis; LeoPARDS) will hopefully help to define its efficacy in septic shock patients. Whether levosimendan has a role in poisoned patients with severe hypotension or shock remains unclear. Importantly, hypotension in the overdose setting is frequently a result of a vasodilatory state – similar to the hyperdynamic state in the peripheral circulatory failure seen in septic patients. In this circumstance, a vasopressor such as norepinephrine (or vasopressin in certain circumstances) will still remain the most appropriate agent to improve blood pressure and systemic perfusion.

There are few reported cases with calcium channel blocker overdose that have been – along with extensive conventional therapy – successfully treated with levosimendan [111, 112]. Although results from animal models of calcium channel blocker and beta-blocker toxicity have shown that levosimendan improves CO, they have not shown that it increases blood pressure [113–116].

Vasopressin Analogues

Vasopressin physiologically mediates its cardiovascular effects via the V_1 receptor. It furthermore stimulates V_2 and V_3 receptors as well as oxytocin and purinergic receptors and thus has a wide range effect on several organ systems [117, 118]. Compared to norepinephrine, it may both modulate

immune function through V_1 receptors and have protective effects on endothelial function. Beside its well-known vasoconstrictive and antidiuretic properties, vasopressin has several other effects on substrate metabolism, mitochondrial function and oxidative phosphorylation, endocrine system, coagulation, liver function and bile flow, electrolytes, thermoregulation, immune function, endothelium, and intestinal motility. These may both explain typical and atypical side effects but also potential desirable effects.

Vasopressin analogues such as arginine vasopressin and terlipressin are increasingly used off-label and may be effective to increase MAP and reduce further catecholamine requirements in catecholamine-refractory (hyperdynamic) peripheral shock, although no overall survival benefit for patients in septic shock has been consistently demonstrated [119].

Experimental and clinical reports have demonstrated hypersensitivity against exogenous vasopressin receptor agonists in refractory peripheral shock, and their administration is associated with a marked increase of MAP and exaggerated elevation of SVR, even after small doses, while efficacy of catecholamines is markedly reduced [120].

In adult septic shock patients, vasopressin doses up to 0.04 IU/min are not reported to be associated with impaired CO or oxygen transport [121]. Furthermore, a multicenter, randomized clinical trial (vasopressin and septic shock trial, VASST) revealed no difference in mortality when comparing vasopressin doses of 0.03 U/min compared to norepinephrine alone, but it proved the safety and efficacy of vasopressin to reduce norepinephrine requirements [119]. The rationale for (additional) vasopressin therapy in vasodilatory shock is to reduce high and potentially toxic catecholamine dosages to ranges with a more reasonable benefit-risk ratio [122]. A cohort study indicated that 0.6 $\mu\text{g/kg/min}$ norepinephrine might constitute such a critical limit [123].

A retrospective analysis suggested that vasopressin doses up to 0.067 U/min may be as safe as a lower dose (0.03 IU/min) but more effective [124]. A more recent meta-analysis and systematic review of literature covering nine randomized

controlled trials with nearly 1000 participants investigated vasopressin and terlipressin in critically ill patients and concluded that vasopressin and terlipressin in vasodilatory shock are safe, associated with reduced mortality compared with norepinephrine, and facilitate weaning of catecholamines. In patients with septic shock, vasopressin compared with norepinephrine may also decrease mortality [125]. The long duration of action of terlipressin (several hours compared to minutes for vasopressin) is believed to offer no advantage over vasopressin and is therefore not recommended [18].

Vasopressin has been used as alternative for intractable hypotension in verapamil poisoning [126], but one animal study in verapamil-poisoned dogs demonstrated worsening of CI and no improvement in MAP [127]. Successful use of PDE-III inhibitors, as well as terlipressin, together with conventional antidotes and catecholamines has been reported in single cases of verapamil or angiotensin-II receptor antagonist overdose [128–130].

However, the use of vasopressin analogues may be linked to severe hemodynamic side effects, including reduced CO, diminished oxygen delivery, and consequently poor perfusion of the skin, gut, and liver [131]. Of note, global markers of impaired tissue perfusion such as lactate (or decreased capillary refilling or mottling) may remain constant and may indicate severe tissue hypoxia [132]. Hyponatremia in response to antidiuresis with water retention, decrease in platelet count, impairment of platelet aggregation, and elevation of liver enzymes and bilirubin may also occur [120, 133]. Dünser et al. reported a significant incidence of thrombocytopenia ($<50,000/\mu\text{L}$) in patients treated with vasopressin (0.067 U/min) but found no difference in the norepinephrine treated group [134]. Occurrence of thrombocytopenia during vasopressor therapy (beyond other reasons, i.e., septic patients) is thus frequent, but the clinical impact unclear.

Taken together, continuous application of vasopressin analogues is preferable over bolus doses, but the dose should not exceed 0.03 (-0.067) U/min for vasopressin or 2 $\mu\text{g/kg/h}$ for terlipressin, respectively [120]. Additional patient-tailored

Table 5 Effects of different catecholamines/inotropes/vasopressors on hemodynamic parameters

Catecholamine	CO	HR	SAP	LVEDP	SVR	CBF	MOD

aggressive fluid resuscitation may prevent adverse hemodynamic side effects of vasopressin analogues. Regular evaluation of ischemic skin lesions seems advisable although the incidence of skin necrosis does not appear to be higher in patients treated with vasopressin analogues compared to single catecholamines [135]. Electrolytes, platelets, and liver function tests together with lactate should be regularly (e.g., every 8–12 h) monitored. In cases of rapid deterioration, vasopressin analogues should be discontinued.

Table 5 shows a summary of typical effects of different catecholamines or inotropes on hemodynamic variables that can be quantified by enhanced hemodynamic monitoring.

Intravenous Lipid Emulsion Therapy

Intravenous lipid emulsion therapy is a proven, beneficial, and life-saving treatment of otherwise irretrievable situations in local anesthetic systemic toxicity (LAST) – however, several case reports, case series, and small studies suggest that it may also be beneficial in lipid-soluble poisonings with severe circulatory shock beyond this indication [136]. The most commonly reported nonlocal anesthetic drugs treated with ILE are tricyclic antidepressants and calcium channel blockers. ILE is recommended by the AHA and the American Society of Regional Anesthesia and Pain Medicine (ASRA) for use in LAST [137, 138] and recommended by the American College of Medical Toxicology for consideration in severe hemodynamic instability resulting from lipid-soluble xenobiotics [139]. Current dosing

recommendations from ASRA for 20% lipid emulsion therapy – which are frequently deduced for the ILE therapy for other xenobiotics – are: bolus 1.5 mL/kg (lean body mass) intravenously over 1 min, repeat the bolus for persistent cardiovascular collapse and continue infusion with 0.25 mL/kg/min for at least 10 min after hemodynamic recovery. The continuous infusion rate can be doubled for persistent hemodynamic instability. The upper limit of ILE recommended by ASRA is 10 mL/kg for the first 30 min, although higher doses of several successfully managed cases with no or minor side effects have been reported [137, 139].

The most commonly proposed mechanisms for the resuscitative effects of ILE are partitioning of the (lipid-soluble) xenobiotic and enhanced cardiac metabolism [140, 141]. The latter is suggested as fatty acids are known to increase cardiac myocyte calcium levels and thus ILE may act via direct inotropic action through increasing intramyocyte calcium concentration [142].

Potentially severe adverse effects such as the inability to obtain reliable complete blood count, interference with colorimetric laboratory tests, pancreatitis, respiratory distress syndrome, interference with vasopressors or other life-saving drugs, enhanced absorption of orally ingested lipophilic drugs, and clot formation during extracorporeal membrane oxygenation have to be carefully weighed against the possible benefits of ILE – even no contraindications are absolute in the setting of cardiovascular collapse [139, 143].

The evidence for the effectiveness of ILE in the overdose setting of xenobiotics other than LAST

in hypotensive patients, patients in severe shock or even cardiac arrest is limited and mostly derived from animal models and anecdotal or single case reports, case series, or small prospective studies. Additionally, it is as yet unclear whether hypotheses derived from LAST can be generalized to other agents of similar lipophilicity and/or inhibition to mitochondrial lipid metabolism [136]. Moreover, attributing causality to ILE in successfully resuscitated cardiac poisonings has been questioned given the confounding effects of numerous prior or concurrent interventions [136, 144]. Finally, there is a high probability of substantial publication bias toward positive effects of ILE. Unfortunately, there is no current prospective controlled randomized trial being undertaken to evaluate the efficacy of ILE [139]. This precludes the use of ILE as a first-line therapy for indications other than LAST.

This topic is discussed in greater detail in ► Chap. 152, “Lipid Resuscitation Therapy.”

High-Dose Insulin in Toxic Hypotension or Shock

There is increasing evidence that high-dose insulin (HDI) therapy (at doses between 1 and 10 units/kg/h) – classically recommended for severe beta-blocker or calcium channel poisoning (and discussed more in depth in the chapters related to these drugs) – may also be beneficial beyond these indications in individual scenarios [79, 81, 90, 145–147]. These reports include successful treatment of amitriptyline, citalopram, and amiodarone overdose when conventional treatment strategies have failed [148, 149].

Insulin has positive cardiac inotropic properties by promoting cellular glucose uptake, activating glucose transporters and both cardiac calcium- and potassium channels, and enhancing aerobic metabolism. It furthermore reactivates the phosphatidylinositol 3-kinase pathway – affecting the synthesis of glycogen and lipids – and it dilates systemic, coronary, and pulmonary vasculature via endothelial nitric oxide synthase [79, 146, 150, 151]. In several intact animal models, HDI (assuming the mechanisms mentioned above

may apply) was shown to be effective in enhancing CO and reducing SVR and thereby improving tissue perfusion [146, 152]. In a blinded, randomized controlled trial, HDI was statistically and clinically significantly superior to placebo in pigs with propranolol-induced cardiogenic shock. Moreover, higher insulin doses (10 vs. 5 vs. 1 unit/kg/h) were more effective at increasing CO than lower doses [80].

Beside the promising treatment option of HDI in cardiotoxic shock caused by beta-blocker or calcium blocker overdose, evidence of efficacy and safety so far is limited to animal models, case reports, small series, or prospective studies. As one size does not fit all, dose ranges of insulin have to be defined for overdoses with individual xenobiotics and as always, potentially severe side effects (including hypoglycemia and/or hypokalemia) have to carefully be outweighed against the potential benefits of this treatment strategy [153]. This especially holds true for the risk of severe hypoglycemia for indications other than calcium channel blocker overdose, as the latter cause insulin resistance, making unrecognized hypoglycemia less likely [154].

This topic is discussed in greater detail in ► Chap. 147, “Euglycemic Insulin Therapy.”

Methylene Blue

Traditionally, methylene blue (MB) has been used as an antidote for either hereditary or toxin-induced methemoglobinemia. It was also been considered for ifosfamide-induced encephalopathy, as an aniline dye derivative, and an antimalarial agent [155]. The use of MB has, however, most recently been advocated as a potential adjunct in the treatment of toxin-induced, anaphylactic, or sepsis-related severe hypotension or shock [156–158].

MB has an estimated terminal elimination half-life of 5.25 h and a volume of distribution of 0.2 L/Kg. Metabolism is predominantly via reduction to leucomethylene blue in peripheral tissues. It is eliminated through the kidneys in about 30% after intravenous and about 20% after oral administration [159]. Typical dosing for MB is

1–2 mg/kg of a 1% solution intravenously, with a repeat dose given if there is inadequate initial response [160]. A continuous infusion after the bolus dose has been described at ranges usually between 0.5 and 1 mg/kg/h. Despite its relatively short biological activity, MB can be present as discoloration in the urine for up to 5 days.

MB is thought to exert its main therapeutic effect in shock states by increasing SVR and reversing myocardial depression [161]. MB inhibits soluble guanyl cyclase (GC) and nitric oxide synthase (NOS) activity. Its inducible form (iNOS) is produced in cardiac myocytes, and vascular smooth muscle produces nitric oxide (NO). NO activates soluble GC producing cyclic guanosine monophosphate (cGMP). Elevated intracellular cGMP leads to relaxation of myocardium and vascular smooth muscle and increases vascular permeability. In summary, inhibition of GC by MB prevents relaxation of vascular smooth muscle (thereby increasing SVR), prevents relaxation of myocardium (reversing myocardial depression), and prevents increased vascular permeability (reversing third-spacing) [160]. In several dose-finding studies, MB has been shown to increase MAP, SVR, and pulmonary vascular resistance [162, 163].

The strongest evidence that MB may be a useful adjunct in raising blood pressure in septic shock patients is provided by two randomized controlled trials. MB, compared to saline, significantly increased MAP, although the effect was transient and MB did not have an impact on survival rates [164, 165].

In a recent case report, Jang et al. reported on the use of MB in the treatment of refractory shock from amlodipine [156]. After consuming 400 mg amlodipine, the patient became severely hypotensive and was treated with high doses of fluids, calcium gluconate, high-dose insulin, glucagon, dopamine, and norepinephrine without substantial effect on the MAP. After a bolus dose of 2 mg/kg of MB over 20 min followed by 1 mg/kg/h intravenously, MAP significantly improved and high-dose insulin together with all vasopressors could be weaned. Although the authors suggested MB as a rescue therapy in the treatment of refractory hypotension in calcium channel blocker

poisoning, a synergistic effect between all of the applied therapies and MB cannot be excluded.

Further evidence suggesting beneficial effects of MB in hypotensive or patients with shock in the overdose setting is limited to very few case reports. In all of these cases, MB was accompanied with other treatment strategies, including vasopressors [160]. This raises the question whether MB has beside synergistic also direct effects on increasing blood pressure – the pharmacodynamic action of MB would suggest the latter.

There are some potential severe adverse reactions of MB that should be considered. Due to an inhibitory effect on the monoamine oxidase, MB has been shown to potentially cause a serotonin syndrome – especially at higher doses of MB (5–7 mg/kg) [166]. MB should, therefore, not be administered in poisonings with serotonergic property [160]. At higher bolus doses (4–15 mg/kg), MB may cause paradoxically methemoglobinemia and due to its effect on pulmonary vasoconstriction, these effects of MB may limit its use in patients with ARDS [167].

MB is discussed further in the chapter on this agent.

Prolonged External Chest Compression Using Mechanical Resuscitation Devices

During cardiac no-flow situations (cardiac arrest, ventricular fibrillation) in the course of poisoning, successful resuscitation requires timely application of high-quality chest compression and/or defibrillation. In animal models of induced ischemic ventricular fibrillation, it has been demonstrated that even during effective and continuous external chest compression, systemic blood pressure did not rise above 40/10 mmHg within the first minute. Furthermore, it may be up to 2 min until adequate left ventricular and aortic pressure could be achieved for sufficient cardiac reperfusion – a prerequisite for successful resuscitation [168]. This implies a need for high-quality external chest compression, and it is questionable whether this could regularly be achieved in prolonged manual cardiac resuscitation

maneuvers that may be indicated for toxin-induced cardiac arrest [169, 170].

The most frequently used and best-evaluated systems are the load distributing band (LDB, AutoPulse[®], Zoll, USA) and the Lund University Cardiac Arrest System (LUCAS[™], Jolife AB/Physio-Control, Lund, Sweden).

Several studies demonstrate an advantage of external mechanical chest compression devices in cardiac arrested patients compared to standard chest compression, both in the preclinical and the clinical setting. However, two very recent randomized studies comparing external mechanical compression devices with standard thorax compression methods did not demonstrate improved survival or neurological outcome in patients treated with such mechanical devices compared to the standard group [171, 172]. A recent Cochrane review concluded that there is currently insufficient data to justify a routine use of mechanical compression devices [173].

It has, however, to be considered that the vast majority of patients in these studies suffered from direct cardiopulmonary complications (e.g., myocardial infarction, pulmonary embolism, or ischemic arrhythmia) and there are only very few single reports or series indicating that prolonged chest compression with mechanical devices may play a role in poisoned patients also [169, 174, 175]. Although uncommon, prolonged cardiopulmonary resuscitation using external mechanical devices has been associated with a favorable outcome in single cases of poisonings [176–178].

Unless more proven evidence about the impact on important clinical outcome parameters is available, the use of mechanical thorax compression devices, such as the LUCAS[™] and AutoPulse[®] system, should be considered if prolonged resuscitation in poisoned patients is indicated. These systems may enable the chance for endogenous and exogenous detoxification processes or may facilitate access to procedures such as extracorporeal life support (ECLS; see below) – with promising survival rates reported in small studies [179, 180]. It may additionally be indicated if the neurological outcome of the cardiac arrested poisoned patient seems promising and ethical issues for prolonged resuscitation seems also to be justified.

Extracorporeal Life Support (ECLS)

There are some cardiotoxics that might particularly be associated with severe hypotension, shock, or even cardiac arrest and the most severely cardiovascular-poisoned patients may not respond to any optimal conventional or reserve intervention as stated above. These patients may need special therapies such as ECLS [181]. ECLS is an umbrella term, including different active (pump driven) and passive (pumpless) techniques: i) the extracorporeal membrane oxygenation (ECMO), of these the veno-arterial (VA-ECMO) form being exclusively used for toxin-induced hemodynamic compromise, as the veno-venous (VV-ECMO) form does not support circulatory insufficiency; and ii) emergency cardiopulmonary bypass (ECPB) [182]. An exemplary simple ECPB/ECMO-configuration is shown in Fig. 3.

Venous blood is withdrawn from a central venous line (e.g., the femoral vein), pumped through a membrane oxygenator (providing gas exchange), and reinfused into a central artery (e.g., the internal carotid artery). This configuration allows – in contrast to veno-venous-ECMO, providing gas exchange only – also circulatory support. A typical recirculation problem occurs, if the drainage catheter and the reinfusion catheter are in close proximity. In this situation, oxygenated blood is being drawn back into the ECMO system without having entered the systemic circulation.

Despite promising results of ECLS performed in small patient groups, there is currently insufficient evidence to recommend the use of ECLS in a setting other than “experimental” [183, 184]. Several case reports and case series demonstrated good neurological outcomes in poisoned patients with prolonged (up to 4 h or longer) cardiopulmonary resuscitation, particularly in tricyclic antidepressant poisoning, beta-receptor, and calcium channel antagonist overdose [181, 185, 186].

Cardiac assist devices, intraaortic balloon pumps (IABP), ECPB, and ECMO have been successfully used to support poisoned patients to recovery and are also stated in the TOX-ACLS guidelines [83, 187–189]. The utility of these

Fig. 3 Exemplary configuration of a veno-arterial emergency cardiopulmonary bypass (ECPB also known as VA-ECMO with kind permission of JACC: Abrams D et al. 2014; 63 (25):2769)

measures will, however, depend finally on the causative agent, local resources, experience, and timing of their institution [190].

The experimental evidence that supports the use of ECLS was provided by six animal studies (LoE IIB) and more than 30 case reports. Few studies using control groups within different animal species, including dogs and swine, support evidence of the efficacy of extracorporeal life support in cardiovascular drug poisoning.

In one study, dogs received bolus doses of lidocaine. The control group (ACLS) was treated with antiarrhythmics, vasopressors, and cardioversion. Six of eight animals died within 30 min after infusion of lidocaine with standard treatment, while none of the dogs in the ECLS group died [191].

In another study with 12 dogs with desipramine-induced cardiac arrest, in addition to conventional measures, six were treated with ACLS using a thumper and six received ECLS therapy. In the ACLS group, return of spontaneous circulation (ROSC) occurred in only 1/6 dog, while 6/6 dogs in the ECLS group had ROSC. Moreover, surviving dogs in the ACLS group needed significantly higher doses of norepinephrine during the observation period [192].

In a third study, 20 swine were poisoned with i.v. amitriptyline (0.5 mg/kg/min) until systolic blood pressure dropped below 30 mmHg. The control group (ACLS) received conventional supportive therapy, including i.v. fluids, sodium

bicarbonate, and vasopressors. Animals failing to respond to ACLS therapy after 5 min additionally received open-chest cardiac massage for 30 min or until ROSC. Animals in the ECLS group received mechanical support only without pharmacological treatment. In the ACLS group, only 1/10 animal could be resuscitated while all 10 animals in the ECLS group had ROSC and nine of them could be easily weaned from bypass [193].

Patients presenting with severe hypotension, shock, or cardiac arrest following drug overdose are commonly younger, have no preexisting comorbidities such as myocardial or renal disease, and neurological outcome of timely and effective resuscitation is likely to be better than that expected in older patients suffering from different causes [2]. Vigorous resuscitation efforts maintaining minimal circulation until the toxin can be eliminated from the body seem therefore warranted and justified in individual situations. Many poisoning deaths are due to severe but potentially reversible depression of cardiovascular functioning and many patients may survive without end-organ damage if adequate perfusion can be maintained [83].

ECLS may further enable time for the normal detoxification methods or metabolism and excretion of the toxin through the liver and kidney. It is, however, yet not known whether ECLS affects drug metabolism or elimination, or whether it can be combined effectively with enhanced

elimination techniques, such as hemodialysis, albumin dialysis, or plasma exchange therapy – all of these requiring a minimal circulation [182].

If these invasive and partially heroic measures are to be effective, they must be implemented in a timely fashion before the stage of irreversible shock has been reached, and they require multidisciplinary expertise, including cardiology, cardiothoracic surgery, and cardiopulmonary perfusion experts (LoE IIb).

Intraaortic balloon pump or counterpulsation (IABP/IABC) provides limited support of CO, increasing it by about 20%. A recent randomized, controlled trial showed no beneficial effect of IABC in patients with cardiogenic shock, and its routine use for this indication is not currently recommended [18, 194]. Evidence for IABP use in poisoning events was provided by one animal study (LoE IIb) [191] and more than 10 case reports (LoE III). It has been used alone for the treatment of life-threatening overdose with quinidine [195], propranolol [196], dextropropoxyphene [197], antihistamines [198], and a combination of verapamil and atenolol [199]. In one case, IABP has been used together with ECLS in organophosphate poisoning [200]. IABP has, however, no role in cases of cardiac arrest, which is a major limitation for the treatment of cardiotoxic poisoning, where cardiac low- or no-flow situations may be observed due to ventricular tachycardia, ventricular fibrillation, electromechanical dissociation, or refractory cardiac arrest [201].

ECPB mainly provides circulatory support and requires always a membrane oxygenator. It further necessitates a sternotomy and both atrial and aortic cannulations. It is an invasive surgical procedure with a number of potentially life-threatening complications (e.g., coagulopathy, hemorrhage, pericardial tamponade). It has been used in single cases of aconitine, diltiazem, and verapamil poisoning [202–204].

ECLS also provides circulatory support but can be performed using peripheral cannulations of both arterial and venous vessels (most frequently the femoral vessels), in contrast to ECPB. As for ECPB, ECLS requires additionally a membrane oxygenator (ECMO). ECLS can

provide flow rates from 1.5 up to 6 L/min and can thus bridge a failing or even arrested heart. Beside several complications of either percutaneous or surgical cannulation, the large diameter of the cannula (15–17 Gauge) can cause critical limb ischemia, which can, however, be prevented by peripheral bypass surgery [205].

ECLS was clinically used in single cases of imipramine, desipramine, carbamazepine, propranolol, acebutolol, disopyramide, quinidine, flecainide, verapamil, diltiazem, carbamate, paroxetine, digoxin, and chloroquine poisoning [181]. For a brief summary, see also [201].

Clinical evidence and efficacy of the extracorporeal assist methods mentioned above is limited to single case reports and small series [181, 206]. A recently published retrospective cohort analysis from two centers in France including 62 patients compared outcome between 14 poisoned patients (mainly antiarrhythmics with membrane stabilizing activity) treated with ECLS and 48 patients treated with conventional therapies. Baseline parameters such as poisoning severity score, simplified acute physiology II-score, sequential organ failure assessment score, and GCS-score were comparable between the groups. Surviving of ECLS-treated patients (12/14; 86%) was significantly higher compared to the conventionally treated group (23/48; 48%) and this result remained significant, even after adjusting for confounders in multivariate analysis [181]. Important to note is that the use of ECLS was complicated by severe ischemia or bleeding, requiring immediate vascular surgery in one third of the cases. There was a trend toward better survival in the subgroup of patients with severe shock (52/62) compared to those with persistent cardiac arrest (10/62). As reported by others, none of the patients with persistent cardiac arrest survived without ECLS [181]. Survival rates of patients within cardiac arrest treated with ECLS seem to be higher (33–71%) compared to conventional treatment without ECLS, where survival rates have been reported as low as 4.5–7.5% [183, 190].

Even though all these case reports and series suggest that ECLS may be promising in patients poisoned with cardiotoxics, they do not allow

drawing any definite conclusions and it is likely that there is a meaningful underreporting of cases that have failed from this invasive procedures. Furthermore, prognostic indicators able to predict refractoriness to conventional treatment are largely unknown.

Finally, utilization and implementation of ECLS is associated with significant financial costs (average total cost approximately US \$ 100,000), and this financial impact has to be considered by the health care community and society [182, 207].

For a further discussion of this topic please see

► Chap. 4, “Extracorporeal Membrane Oxygenation and Cardiopulmonary Bypass in the Poisoned Patient.”

Conclusion

In cases of poison-induced refractory cardiac arrest or refractory heart failure, exceptional therapies may be considered [201], such as:

- (Ultra-) high-dose catecholamines, ILE, HDI, levosimendan, or other PDE-III-inhibitors
- Prolonged external chest compression with the use of mechanical devices, e.g., AutoPulse® or Lund University Cardiopulmonary Assist System (LUCAS 2®) in cases of cardiac arrest
- ECLS if heart failure, multi-organ failure, or cardiac arrest develops
- ECPB in patients with history of severe arteritis or lower limb ischemia if ECLS with the need for arterial cannulation is not feasible

In cases of refractory peripheral vasoplegia:

- Increased doses of vasopressors (e.g., epinephrine or norepinephrine, consider vasopressin)
- Consider application of methylene blue

The constancy of the internal environment is the condition for free and independent life.

Claude Bernard, 1813–1878

Acid–base disorders are a major source of morbidity and mortality among patients in the intensive care unit (ICU). An observational cohort study of 9,799 ICU patients found that nearly two thirds of critically ill patients suffered from acute Metabolic Acidosis. Mortality among those with metabolic acidosis was 45% compared with 25% for those without it. For those with lactic acidosis, the mortality rate was 56% [1]. It is difficult to directly extrapolate these findings to poisoned patients who generally have a significantly lower mortality rate than the average ICU patient. We do know, however, from studies of poisonings with specific substances, such as metformin, ethylene glycol, and methanol, that the presence of severe metabolic acidosis is associated with a relatively poor prognosis [2]. A review of 22 cases of metformin overdose revealed a median pH nadir of 7.30 and median plasma lactate of 10.8 mmol/L among survivors compared with pH 6.71 and median plasma lactate of 35.0 mmol/L among non-survivors [2]. Among 18 ethylene glycol poisoned patients, non-survivors had a mean admission pH of 7.05, compared with 7.31 in survivors [3]. No patient with a pH less than 7.10 survived. Not surprisingly, most of the non-survivors presented to the hospital late after ingestion (from 6 h to >24 h). In a review of one-time methanol exposures with

TX, USA
e-mail: stephen.borron@ttuhsc.edu

known time of ingestion, 22 patients presented for care <6 h after ingestion and had an early methanol level. Sixteen of these were acidotic on arrival [4]. Blood methanol concentrations ranged from 10 to 570 mg/dL (3–178 mmol/L), and initial arterial pH ranged from 6.90 to 7.42. All underwent treatment with alcohol dehydrogenase inhibitors (with or without hemodialysis). One patient with pH 6.99 died. Three patients with pH ranging from 7.26 to 7.32 suffered optic neuropathies but survived. One patient with pH 6.90 was described as “alive” on discharge, with the remaining 11 (pH range 7.09–7.42) noted as having a full recovery. In summary, it appears that severe metabolic acidosis is associated with a poor prognosis in representative poisonings and that time of presentation plays a significant role in outcome. A larger study of the prognostic value of acid–base disturbances in poisoning in general among ICU patients would be edifying.

In poisoning, alterations of acid–base balance may result from exogenously administered ions, metabolic production of organic acids, impaired mitochondrial function, renal injury, hypoventilation, or inadequate tissue delivery of oxygen because of respiratory or circulatory insufficiency. Poisoned patients may suffer acid–base disturbances due to underlying illness or complications of their hospitalization, including acute or chronic kidney or pulmonary disease, side effects of therapy (crystalloids, diuretics, hyperalimentation, vasopressors), and sepsis. Determining which disorders of acid–base balance are present, and which are due to the toxic exposure versus underlying illness or complications, is not always straightforward. Thus, it is incumbent on critical care physicians caring for poisoned patients to be well versed in the evaluation and management of disorders of acid–base equilibrium.

In the last edition of this text, a “quiet revolution” was ongoing in acid–base disorder analysis, as exemplified by increasing attention to the work of Stewart with respect to electroneutrality and the strong ion gap. In the intervening period, numerous evaluations of the Stewart method have been undertaken, rendering examples of complex acid–base disorders discerned by quantitative

acid–base chemistry that might have been missed by the standard approach using base excess. It is fair to say that this issue remains highly controversial, with two very staunch camps, the “bicarbonate-based camp” and the “Stewart camp.” According to Rastegar, the Stewart approach has been largely ignored by nephrologists and renal physiologists while being embraced by anesthesiologists and intensivists [5]. He opines that the Stewart method provides no advantages over the traditional method in terms of prognosis. While numerous small prospective studies have compared these methods, large multicenter comparisons are lacking, and so the argument is not likely to be settled soon. It may be said, however, that the Stewart approach has led even the traditionalists to reexamine the importance of the influence of nonvolatile buffers, such as albumin, as well as the effects of dilution on the standard base excess and on the anion gap, resulting in new corrective formulas even in the “traditional camp.” On the quantitative acid–base side, investigators have attempted to distance themselves from tedious formulas and exhaustive analyses, offering simplified formulas and confining their components to plasma elements that most often undergo significant alteration. Al-Jaghbeer and Kellum argue that the two approaches are complementary and not contradictory [6]. Both approaches to acid–base analysis are discussed in this chapter.

Rapid Review of Key Factors in Acid–Base Equilibrium

Acid–base balance under physiological conditions is the simple sum of the production of organic acids occurring in metabolism and their elimination or neutralization by the body’s buffer systems. The first line of defense is the respiratory buffer system. Carbon dioxide, produced by the metabolism of carbohydrates, forms carbonic acid (H_2CO_3) when combined with water:

This is considered an “open system” because moderate increases in CO_2 are normally eliminated by a compensatory increase in minute volume. Acidosis stimulates respiratory chemoreceptors to produce an increase in ventilation, hence shifting this equation to the right and thus reducing the acidosis. However, severe acidosis may actually impede ventilation and lead to a vicious cycle that may result in death unless rapidly corrected.

Plasma proteins and phosphate stores in the bone serve as a second line of defense against acid–base abnormalities. The important role of these buffer systems will be discussed further with the “strong ion” approach. A strong ion refers to one that generally exists in a dissociated or nearly dissociated form (Na^+ , K^+ , Cl^- , and others). The kidneys play a critical role in acid–base balance via regulation of strong ions.

All forms of acid–base disorders may be observed in a poisoned patient. However, given its frequent presence in serious poisonings, the majority of this chapter will be devoted to metabolic acidosis.

Toxicant-Induced Respiratory Alkalosis and Acidosis

Respiratory alkalosis and acidosis are direct reflections of increased and decreased ventilation, respectively. Ventilation may be altered through changes in tidal volume, respiratory rate, and gas exchange across the alveoli or by combinations thereof. These disorders may be of central or peripheral origin. Stimulation of the central nervous system may result in tachypnea or hyperpnea and subsequent respiratory alkalosis. Salicylates [7], nicotine [8], and caffeine [9] are examples of agents that stimulate respiratory centers. Opiates decrease the respiratory rate by depressing the central respiratory and brainstem regulatory centers, [10] but also reduce ventilation through peripheral effects, such as non-cardiogenic pulmonary edema and increases in thoracic muscle tone [11]. Benzodiazepines and barbiturates likewise have both central effects (γ -aminobutyric acid-mediated depression in the medulla

oblongata) and peripheral effects (muscle weakness resulting in upper airway obstruction and/or respiratory muscle inefficacy); however, the peripheral effects appear to be of greater clinical importance [12]. Inadequate ventilation may also result in inadequate oxygenation and thereby lead to anaerobic glycolysis and lactate production. Thus, combined respiratory and metabolic acidosis is not uncommon in poisoning by toxicants that interfere with ventilation. Clinical diagnosis of these disorders is rather straightforward and based on physical examination and arterial blood gases, particularly PaCO_2 .

Toxicant-Induced Metabolic Alkalosis

Chemical-induced metabolic alkalosis is relatively rare. The milk-alkali syndrome, characterized by hypercalcemia, metabolic alkalosis, and renal failure, was common in the early to mid-twentieth century, when a common remedy of peptic ulcer disease consisted of hourly administration of milk with a “Sippy” powder (sodium bicarbonate with calcinated magnesia or bismuth subcarbonate) [13]. Nowadays, it is seen most often in elderly women taking calcium supplements for osteoporosis and among patients taking calcium antacids and is rightfully known as calcium-alkali syndrome [13, 14]. It has also been reported in betel nut chewers who use calcium-rich oyster shell paste in its preparation [15]. Laxatives taken in excess can give rise to hypokalemia and metabolic alkalosis [16, 17], as can diuretics [18, 19] and licorice [20, 21]. A non-exhaustive list of toxicants responsible for metabolic alkalosis is found in Table 1.

Toxicant-Induced Metabolic Acidosis

Acute metabolic acidosis is found in 64% of critically ill patients. Its presence is associated with an almost twofold rise in mortality [1]. Al-Jaghbeer and Kellum divide the causes of acidosis into (1) increased anion gap and (2) non-anion gap, consisting of renal, gastrointestinal, and iatrogenic causes (Box 1). While

Table 1 Toxicants reported to cause metabolic alkalosis

Agent	Classification	Selected references
Amikacin	Aminoglycoside antibiotic	[22]
Calcium carbonate	Antacid	[23]
Chlorthalidone	Diuretic	[24]
Ethacrynic acid	Diuretic	[19, 25]
Furosemide	Diuretic	[25]
Gamma-hydroxybutyrate	Anesthetic	[26]
Gentamicin	Aminoglycoside antibiotic	[27, 28]
Laxative	Laxative	[16, 17]
Licorice (glycyrrhizin)	Candy	[20, 21]

Hyperchloremic (non-anion gap)
Renal tubular acidosis
Gastrointestinal
Diarrhea
Small bowel/pancreatic drainage
Iatrogenic
Parenteral nutrition
Saline
Carbonic anhydrase inhibitors
Anion-exchange resins

Many toxicants provoking acidosis increase the anion gap. Ingested mineral acids (toilet bowl cleaners, battery acid) may serve as exogenous sources of metabolic acidosis. Toxic alcohols and glycols, including methanol and ethylene glycol, are notable causes of metabolic production of organic acids. Interference with mitochondrial function results in lactate production. Anti-retroviral medications and cyanide are well known for their ability to induce lactic acidosis. Agents causing profound cardiovascular collapse, such as chloroquine and colchicine, may give rise to acidosis through diminished perfusion, as well as other mechanisms. In Table 2, the reader is provided with selected references for a non-exhaustive list of toxicants that may induce metabolic acidosis. In-depth discussion of individual toxicants is beyond the scope of this chapter. Related chapters in this text pertaining to specific substances should be consulted.

Clinical Suspicion of Acid–Base Disorders

Vigilance is required to promptly detect and treat acid–base disorders. The finding of altered mental status or abnormal vital signs should always invoke

Table 2 Toxicants reported to cause metabolic acidosis

Agent	Classification	Selected references
1-Benzylpiperazine (BZP)	Sympathomimetic, stimulant drug of abuse	[35]
2,5-Dimethoxy-4-bromoamphetamine (DOB)	Sympathomimetic, stimulant and hallucinogenic drug of abuse	[36]
3,4-Methylenedioxymethamphetamine (MDMA)	Sympathomimetic, stimulant drug of abuse	[37, 38]
Acetaminophen (paracetamol)	Analgesic, antipyretic	[39]
Acetazolamide	Carbonic anhydrase inhibitor	[40]
Acetonitrile	Solvent, chemical intermediate	[41]
Acetylene	Welding gas	[42]
Aminocaproic acid	Hemostatic	[43]
Amphetamine and substitutions	Sympathomimetic, stimulant drugs of abuse	[37, 44]
Arginine	Amino acid	[45]
Aspirin (acetylsalicylic acid) and salicylates	Analgesic, antipyretic	[7]
Azide, sodium	Herbicide, fungicide, fumigant, bactericide, chemical intermediate, preservative, propellant	[46, 47]
Boric acid	Insecticide	[48]
Carbon monoxide	Asphyxiant, chemical	[49–52]
Cathinones, substituted	Stimulant drugs of abuse	[53]
Chlorine	Disinfectant, halide	[54]
Citalopram	Antidepressant	[55]
Cocaine	Anesthetic, sympathomimetic, stimulant drug of abuse	[56, 57]
Cyanide (HCN and salts)	Asphyxiant, chemical	[58–61]
Detergent sacs, single use (SUDS)	Detergent, laundry and surfactants	[62, 63]
Diazepam	Sedative hypnotic	[64]
Dicamba	Herbicide	[65]
Didanosine	Antiviral, nucleoside analogue	[66, 67]
Diethylene glycol/triethylene glycol	Glycol, solvent, brake fluid	[68–71]
Endosulfan	Organochlorine insecticide	[72, 73]
Ethanol	Alcohol	[74]
Ethylene glycol	Antifreeze, solvent	[70, 75, 76]
Ethylene glycol monobutyl ether (EGBE, butoxyethanol, butyl cellosolve)	Solvent, glass cleaner	[70, 77–79]
Ethylene glycol monomethyl ether (EGME, methoxyethanol, methyl cellosolve)	Solvent, antifreeze	[80]
Etomidate	Anesthetic	[81–84]
Fialuridine	Antiviral, nucleoside analogue	[85, 86]
Flumequine	Antimicrobial, fluoroquinolone	[87]
Formalin (40% formaldehyde in water)	Tissue fixative, embalming fluid	[88]
Formic acid	Organic acid	[89, 90]
Hydrogen sulfide	Petroleum production, decomposition of sulfur-containing organic matter	[91, 92]
Iron	Mineral supplement	[93, 94]
Isoniazid (INH)	Antimicrobial, antitubercular	[95, 96]
Lorazepam	Sedative hypnotic	[97–99]
Mephedrone	Sympathomimetic, stimulant drug of abuse	[100]

(continued)

Table 2 (continued)

Agent	Classification	Selected references
Methamphetamine	Sympathomimetic, appetite suppressant, stimulant drug of abuse	[101]
Methyl alcohol (methanol)	Solvent, antifreeze, chemical intermediate, paint remover	[70, 102]
Methylone	Sympathomimetic, stimulant drug of abuse	[103]
Nalidixic acid	Antimicrobial, quinolone	[104]
Neem oil	Tree oil used in cosmetics, organic gardening	[105, 106]
Nitroprusside, sodium	Antihypertensive, vasodilator	[107]
Nortriptyline	Cyclic antidepressant	[108]
Olanzapine	Antipsychotic, atypical	[109]
Parathion	Pesticide, organophosphate	[110]

Phentermine–topiramate	Appetite suppressant drug combination	[113]
Phosphoric acid	Metal cleaner, toilet bowl cleaner	[114]
Phosphorus, elemental	Pesticide, fireworks	[115]
Potassium chloroplatinite	Photographic toner solution	[116]
Propionitrile	Cyanogen	[117, 118]
Propofol	Anesthetic	[119]
Propylene glycol	Solvent, pharmaceutical adjuvant	[71, 98, 99]
Smoke, fire (see cyanide and carbon monoxide above)	Environmental toxicant	[58, 61, 120]
Sodium chloride	Electrolyte	[121–123]
Stavudine	Antiviral, nucleoside analogue	[124]
Teniposide	Anticancer chemotherapeutic agent	[125]
Theophylline	Thioxanthine bronchodilator	[126]
Thiamine deficiency	Vitamin	[127]
Toluene	Solvent, aromatic organic, paints, thinners, lacquers, adhesives	[128]
Topiramate	Anticonvulsant	[129]
Treosulfan (dihydroxybusulfan)	Anticancer chemotherapeutic agent	[130]
Trimethoprim/sulfamethoxazole	Antimicrobial, sulfonamide	[131]
Valproic acid	Anticonvulsant	[132]
Xylenol	Phenolic detergent	[133]
Zidovudine	Antiviral, nucleoside analogue	[134, 135]

consideration of an acid–base disturbance. Clinical findings may be subtle early in the pathophysiologic process, so habits as elemental as truly counting the respiratory rate may make the difference in early recognition of these disorders. A thorough examination may detect sentinel breath odors (ketones, paraldehyde, and cyanide), altered respiration (hyperpnea, Kussmaul respirations), cyanosis, pressure sores or bullae suggestive of

rhabdomyolysis, etc. Clinical signs and symptoms are insensitive, however, so laboratory screening is necessary in all critically ill patients. While point-of-care diagnostic devices have simplified life for the clinician, a multitude of conditions can alter their readings [136–139]. Definitive evaluation of acid–base disorders is based on carefully selected data provided by the chemistry and toxicology laboratories.

Laboratory Diagnostic Tools in Acid–Base Balance

Gaps in Our Knowledge of Acid–Base Disturbances

This double entendre is not original [140] but reflects our incomplete comprehension of acid–base disorders in spite of years of studies and discussions regarding the use of various gaps – base excess, anion, delta, and osmol. Each of these tools, their potential utility, and their shortcomings will be discussed, followed by a discussion of the quantitative approach to acid–base balance, which introduces the more recent strong ion gap.

Given the ubiquity of its use in clinical medicine, the most frequently available laboratory indicator of acidosis is the serum electrolyte panel. For this reason, anion and delta gaps will be discussed before base excess and osmol gaps.

Anion Gap

The serum anion gap (AG) remains a useful but only moderately sensitive tool in the initial evaluation of potential acid–base disturbances. It suffers from numerous limitations, which will be discussed. If the clinician is aware of these limitations and adjusts for them accordingly, the AG provides one of the most rapidly available tools in the evaluation of acid–base disorders.

In its most basic form,

$$\text{AG} = \text{Measured serum cations} \\ - \text{Measured serum anions}$$

Because the most important anions after chloride and bicarbonate (protein, inorganic phosphate, and sulfate) are not routinely measured in a serum electrolyte panel, a “normal” AG exists. The presence of additional unmeasured anions (often organic acids) creates an “increased” AG. The most commonly used calculation for AG is (using mmol/L units for the anions/cations)

$$\text{AG} = \text{Na}^+ - (\{\text{Cl}^-\} + \{\text{HCO}_3^-\}) \quad (2)$$

An alternative, though less frequently used, equation adds $[\text{K}^+]$ to the first term. Extremes of potassium may affect the AG and should be kept in mind; however, the discussion that follows will be based on (Eq. 2). Although its calculation is remarkably simple, its interpretation is not always straightforward.

Because of the body’s requirement for electroneutrality, an increase in unmeasured anions (the AG) should be compensated by an equal decrease in serum bicarbonate or chloride, although in almost all circumstances, the compensation is reflected in a decrease in the bicarbonate concentration [141]. Thus, the first evaluation of the calculated AG should be its relationship to serum bicarbonate. In the simplest case, AG increases in an amount equivalent to the fall in bicarbonate. However, this does not always occur. For example, in the case of diabetic ketoacidosis (DKA), a discordance is often found [142], with AG being smaller than predicted based on the decrease in bicarbonate. Extensive tubular elimination of ketone bodies, along with concomitant retention of chloride, may result in a component of hyperchloremic metabolic acidosis, thus decreasing the AG. The hyperchloremic component of acidosis increases over the course of DKA [143], probably in part due to the large amount of sodium chloride typically administered in DKA. Large-volume fluid resuscitation with isotonic saline can induce acidosis because the equimolar concentrations of sodium and chloride in normal saline (155 mmol/L) will increase plasma chloride to a greater extent than plasma sodium, thus decreasing the serum bicarbonate concentration [144]. A review of several studies on acidosis induced by chloride-rich crystalloids appears in the discussion on treatment [123].

The limitations of the AG fall into two general categories: (1) analytic and (2) physiologic.

Analytic Limitations and Errors

Early published normal ranges of AG values, 12 ± 4 mmol/L [145], continue to be used by

many clinicians. However, these values now represent, in many hospitals, a significant overestimate because of changes in technology that occurred in the 1980s. Ion-specific electrode methodology has largely replaced flame photometry for measurement of sodium and chloride, leading to an increase in normal values of chloride of 2–6 mmol/L, with a concomitant decrease in the normally expected AG. Winter and colleagues [146] found a normal AG of approximately 6 mmol/L, with 95% confidence intervals of 3–11 mmol/L in a group of 120 blood donors. This difference from previous normal values may seem small, but as the authors point out, if the true normal AG is 6 mmol/L, a patient with 10 mmol/L of added organic acid and thus an AG of 16 mmol/L would, by generally accepted standards, have a normal AG. In a group of 222 patients with normal renal function and albumin, Sadjadi [147] found an AG of 6.6 ± 2 mmol/L, almost identical to that demonstrated in the study of Winter and coworkers. Failure to take this change into account may result in failure to diagnose acidosis. Using a “normal” range of 12 ± 4 mmol/L, Iberti and colleagues found that 50% of critically ill patients with lactic acidemia in the range of 5–9.9 mmol/L and 79% of those with lactate concentrations 2.5–5 mmol/L had AG values less than 16 mmol/L. Applying the current lower ranges of AG would clearly improve sensitivity. Sadjadi and colleagues more recently retrospectively reviewed the charts of 409 veterans with a glomerular filtration rate ≥ 60 mL/min/1.73 m² body surface area and serum albumin ≥ 4 g/dL. They found a mean anion gap of 7.2 ± 2 mEq/L. This compares with 299 patients in the same study with lactic acidosis (lactate ≥ 4 mEq/L) and 68 patients with end-stage renal disease on dialysis, in whom the mean anion gaps were 12.5 mEq/L and 12.4 mEq/L, respectively [148]. A word of caution is in order, however. Lolekha points out that to interpret the anion gap accurately, one must use an analyzer-specific reference range. He and his colleagues found slightly differing anion gaps on four auto analyzers, using blood samples from healthy volunteers [149]. Anion gap values may also vary significantly according to the laboratory

providing the measurements [150]. Finally, clinicians must also be aware that some laboratories have altered the calibration of the chloride-measuring instrument so that the normal ranges of chloride and AG in those institutions remain closer to “classic” published values. Thus, it is imperative that clinicians discuss this issue with laboratory medicine specialists in their own institutions to ensure that the normal ranges provided by the laboratory have, in fact, been verified in that laboratory.

Kraut and Nagami [151] attempted to determine the sensitivity of the AG in detecting lactic acidosis through a literature review. Unless the AG is corrected for serum albumin, the sensitivity ranged from 39% to 63% for serum lactate greater than 2.5 mmol/L. With correction for albumin, the sensitivity range improved to 75–94% demonstrating two salient points: (1) if the anion gap is to be useful, it should be corrected for serum albumin and (2) if one is truly concerned about lactic acidemia, a serum lactate should be obtained. One last word about the anion gap, which applies to lab tests in general: a single, normal AG is just that – a unique, not analytically infallible, test obtained at a point in time. In contrast, poisonings are dynamic processes which may radically modify the kinetics of absorption, distribution, metabolism, and excretion. Jacob et al. recently reported two cases of life-threatening salicylate poisoning with apparently normal anion gap due to a false increase of measured chloride in the presence of high serum salicylate levels on some analyzers [152]. Herres and colleagues reported a fatal case of salicylate poisoning who presented with a deceptively mild elevation in anion gap and initially undetectable serum salicylate concentration. Failure to repeat the anion gap in a timely manner, to trend salicylate concentrations until they were clearly declining, and to carefully observe the patient in an acute medical setting contributed to his ultimate demise [153].

Physiologic Limitations

Serum albumin. Whereas the potential for abnormal proteins (such as cationic multiple myeloma proteins) to alter the AG is widely appreciated, the

critical role of normal proteins such as albumin remains largely ignored. Albumin constitutes the largest component of unmeasured anions under normal physiologic conditions, with inorganic phosphate and sulfates representing most of the remainder. Calculation of the AG without consideration of serum albumin may be justifiable in normal healthy patients, but it is certainly not acceptable in the critically ill. Figge and coworkers found marked hypoalbuminemia in 96% of 152 critically ill patients, with values < 20 g/L (normal range 44 ± 3 g/L) in 49%. Each g/L decrease in serum albumin caused the observed AG to underestimate the total concentration of unmeasured anions by 0.25 mmol/L [154]. A severely malnourished patient may have a significant AG virtually obscured because of the influence of hypoalbuminemia [155]. The AG may be corrected for hypoproteinemia as follows:

$$\begin{aligned} \text{AG}_{\text{corrected}} = & \text{Na}^+ - (\{\text{Cl}^-\} + \{\text{HCO}_3\}) \\ & + 0.25 \times (\{\text{Normal albumin g/L}\} \\ & - \{\text{Observed albumin g/L}\}) \end{aligned} \quad (3)$$

If albumin values are reported in grams per deciliter, the factor is 2.5. Hyperalbuminemia from severe dehydration (cholera) may reach significant enough concentrations to contribute to metabolic acidosis [156].

Water excess/deficit. Significant loss or gain of free water will alter serum sodium and chloride by the same percentage but not by the same absolute amount, which will clearly alter the AG [140]. The effect of hyponatremia (water excess) on the AG has been clinically documented [140, 157]. Decaux and Musch compare the electrolytes and anion gap in various states of hypoosmolality (Table 3) [158]. Corrections for the effects of water excess/deficit are taken into account in calculation of the strong ion gap (to be discussed) but have not generally been applied to the AG. A prospective look at the value of such a correction in patients with metabolic acidosis is needed.

Assumptions regarding lactate in the anion gap. The presence of an increased AG acidosis

not explained by the presence of ketoacids, renal failure, or historical and laboratory evidence of toxicant ingestion is often assumed to be due to lactate. However, Gabow and colleagues found that a measured increase in lactate of greater than 4 mmol/L was present in only 9 of 21 patients (43%) meeting these criteria, thus illustrating the potential for error in such an assumption [145]. Conversely, Dorwart and Chalmers found normal AGs in 32 of 45 patients with plasma lactate levels between 2.5 and 9.9 mmol/L [159]. Thus, if lactic acidemia is in the differential diagnosis, lactate should be quantified. This is particularly important in poisoning, where measurement of exogenous anions such as oxalate or formate is not always readily available. Quantification of lactate may not only provide clues to the diagnosis but also increase or decrease the suspicion of the presence of other unmeasured anions and should thus be considered an integral part of the laboratory evaluation.

Readers should be aware of other worrisome analytical problems related to lactate. Multiple authors have reported falsely elevated plasma lactate in the setting of glycol poisonings. In the case of ethylene glycol overdose, the glycolate metabolite can cross-react with the recombinant L-lactate oxidase, resulting in a marked false increase in measured lactate [160–165], potentially obscuring the diagnosis of ethylene glycol poisoning. D-lactate, a by-product of propylene glycol, can also be falsely recognized by lactate analyzers as L-lactate [166].

Role of potassium in the anion gap. Serum potassium, as mentioned earlier, is often “discarded” in calculating the AG because the range of serum potassium in most patients is small enough that potassium variations cause only a minimal change in the calculated gap. Nonetheless, there are circumstances (e.g., digitalis and toluene poisoning or acute renal failure) in which extremes of serum potassium may occur and render its consideration in calculation of the AG more important. Furthermore, a reduction in “normal” mean AG (absent the potassium) from 12 to 6 mmol/L renders the variation in potassium of greater importance in terms of percent change

Table 3 Clinical and biological data generally allowing differentiation between appropriate and inappropriate Anti-DH secretion in patients with hypoosmolality^a (Adapted from Decaux and Musch [158] with permission)

Parameter	Appropriate diuresis		Inappropriate diuresis
	Hypervolemic (↑ECV; ↓EABV)	Hypovolemic (↓ECV; ↓EABV)	Euvolemic (↑ECV; ↑EABV)
History	Chronic heart failure, cirrhosis, nephrosis	Extrarenal losses (e.g., gastrointestinal, sweating, burns, third space) Renal losses (e.g., Addison, diuretics, bicarbonaturia, salt-losing nephropathy, cerebral salt-wasting syndrome)	Drugs (e.g., carbamazepine, SSRI) Neurologic diseases (e.g., encephalitis, strokes) Pulmonary diseases (e.g., tuberculosis, pneumonia) Cancer (e.g., oat cell carcinoma) Endocrine (e.g., hypothyroidism, pituitary hypocorticism)
BP	Low	Low	Normal
Edema	+	—	—
Plasma anti-DH	↑	↑	↑ (↓ ^b)
Plasma sodium	↓	↓	↓
Plasma urea	NL-↑	NL-↑	NL-↓
Plasma anion gap	NL-↑	NL-↑	NL-↓
Urine osmolality	↑	↑	↑
Urine sodium (mEq/L)	<30	<30 ^c	>30 ^d
Fractional excretion of sodium (%)	<0.5	<0.5 ^c	>0.5 ^d

^aAnti-DH antidiuretic hormone, ECV extracellular volume, EABV effective arterial blood volume, NL normal, SSRI selective serotonin reuptake inhibitor

^bAnti-DH is low in nephrogenic syndrome of inappropriate antidiuresis (nephrogenic syndrome of inappropriate antidiuresis or syndrome of inappropriate secretion of antidiuretic hormone type D)

^cUnless salt depletion is of renal origin

^dIf salt intake is normal

in AG. Regardless of whether potassium is included in the calculation used, it exerts an electrical force as a strong ion.

Hyperphosphatemia. Because the contribution of inorganic phosphates to the normal AG is moderate and because normal phosphate concentrations are generally about 1.0 ± 0.2 mmol/L, hypophosphatemia results in a negligible change in the AG. On the other hand, conditions that result in hyperphosphatemia, such as phosphate enema intoxication, may result in an increased AG [167, 168]. Thus, hyperphosphatemia must be added to the differential diagnosis of an increased AG.

Delta Gap

Another method of evaluating acid–base disorders is to compare the change in AG with the change in alkaline reserve [141]. This relationship is expressed as the “delta gap,” which is defined as:

$$\Delta\text{Gap} = \Delta\text{AG} - \Delta\text{HCO}_3^- \quad (4)$$

where ΔAG is the observed AG minus the upper normal limit of the AG and ΔHCO_3^- is the lower normal HCO_3^- minus the observed HCO_3^- . The normal range for the delta gap is 0 ± 6 . As

mentioned previously, the body must maintain electroneutrality, so an increase in unmeasured anions (the AG) should be compensated by an equal decrease in serum bicarbonate [141]. Therefore, for a simple increased AG acidosis, the delta gap should be 0. A significantly positive (greater than +6) delta gap suggests the presence of metabolic alkalosis. A significantly negative (less than −6) delta gap suggests hyperchloremic acidosis. Because normal values for electrolytes (and AGs) vary among hospitals, depending on the methodologies used, it is imperative to calculate these values on the basis of local norms. Wrenn demonstrated through a series of clinical cases that the delta gap can assist in the detection of mixed acid–base disorders that would go unsuspected on the basis of evaluation of the AG alone. It is not foolproof, however, as illustrated by one case in which a patient with a normal AG (4 mmol/L), a normal delta gap (−2 mmol/L), and a bicarbonate concentration of 19 mmol/L actually had a combination of anion gap metabolic acidosis, HCMA, and metabolic alkalosis from volume contraction [141]. While this simple calculation remains a useful screening tool for distinguishing and mixed acid–base disorder from isolated anion gap acidosis [169], one should not rely entirely on either the AG or the delta gap in the evaluation of potential acid–base disorders [140].

Base Excess

Base excess (BE) was the first “gap” to be proposed as a useful approach to the evaluation of acid–base disturbances [170]. It is calculated as follows, but is often provided with the results of the blood gas analyzer:

$$\text{BE} = 1.2(\{\text{HCO}_3^-\} - 22.9) \quad (5)$$

The multiplier 1.2 takes into account the approximately 25% of buffer capacity not provided by the carbon dioxide/bicarbonate system. HCO_3^- is the “standard” bicarbonate, which is the concentration of bicarbonate in plasma when whole blood has been equilibrated at a PaCO_2 of

40 mmHg, oxyhemoglobin saturation of 100% and temperature of 37 °C. Once the pH is measured, the standard bicarbonate can be obtained directly from (Eq. 6), the Henderson–Hasselbalch equation:

$$\text{pH} = 6.10 + \log \frac{\text{HCO}_3}{\text{PaCO}_2 \times 0.030} \quad (6)$$

The normal mean of standard bicarbonate is 22.9 mEq/L, so this value is subtracted in (Eq. 5) from the product to obtain the BE. A BE less than −5 mEq/L is thought to be consistent with metabolic acidosis. Salem and Mujais have warned against the use of this theoretical bicarbonate concentration when calculating the AG (in lieu of total CO_2) because rapidly changing conditions in apparent values of pK' (the pH at which equal concentrations of the acid and base forms of a buffer are present – range: 5.8–6.3) may result in calculated errors in HCO_3^- as high as 50% [140]. Others have likewise called attention to this problem [171, 172]. Furthermore, excess heparin in blood gas samples may decrease PaCO_2 by up to 25% which also distorts the calculated bicarbonate value [140]. The effects of heparin volume on PaCO_2 have recently been shown to vary with syringe volume, needle size, and sample volume [173]. It stands to reason that the BE, determined on the basis of calculated bicarbonate, also risks misinterpretation. In addition to the risk of analytical and calculated errors, the BE is dependent on a number of other factors “assumed” to be normal in this simple calculation: normal water content, electrolytes, and albumin. As pointed out by Balasubramanyan and colleagues, changes in these values will alter the calculated BE independent of changes in lactate, bicarbonate, or unmeasured anions [174].

Quantitative Acid–Base Analysis: The Strong Ion Gap

The strong ion approach to acid–base management appears to be the most fundamentally sound from the perspective of physical chemistry

[175]. This method, originally described by Stewart [176] and refined by Fencel and Leith [177], relies on the fact that systems operate under a number of restraints imposed by physical laws that must always and simultaneously be met:

1. Electroneutrality must always exist: the sum of all positive charges must always be equal to the sum of all negative charges.
2. Dissociation equilibria of all incompletely dissociated substances must always be satisfied.
3. Mass is conserved; that is, the total concentration of an incompletely dissociated substance can always be accounted for as the sum of the concentrations of its dissociated and undissociated forms. The hydrogen ion concentration in blood is held within a very tight range, 36–43 nmol/L, because this range is critical to the maintenance of appropriate protein function (enzymes, pumps, etc.) and thus cellular function [175]. The source of hydrogen ions is the dissociation of water. Dissociation of water into hydrogen and hydroxyl ions is determined by three independent determinants (each can be changed independently of the others): the strong ion difference [SID], PaCO_2 , and the total weak acid concentration (A_{TOT}).

The first independent variable is [SID], or the net electrical charge difference of the strong ions (i.e., those that are completely or nearly completely dissociated). This variable comprises the strong cations (Na^+ , K^+ , Ca^{2+} , Mg^{2+}) and the strong anions (Cl^- and other strong anions of low pK_a such as lactate and ketoacids), which are likewise almost completely dissociated at physiologic pH. The second independent variable is PaCO_2 , which, of course, varies with ventilation. The third independent variable is A_{TOT} , the sum of weak acids [HA] and their anions $[\text{A}^-]$. The weak acids are primarily composed of proteins (mainly albumin) and inorganic phosphates $[\text{Pi}^-]$. Kellum and coworkers [178] point out that weak acids [HA] without their anions are not an independent variable because their equilibrium with A^- changes with alterations in [SID] and PaCO_2 . Looking at Fig. 1, one observes that the [SID] can also be calculated by adding the $[\text{HCO}_3^-]$ to

Table 4 Classification of primary acid–base disturbances

	Acidosis	Alkalosis
I. Respiratory	$\uparrow \text{PaCO}_2$	$\downarrow \text{PaCO}_2$
II. Nonrespiratory (metabolic)		
1. Abnormal [SID] ^a		
a. Water excess/deficit ^b	$\downarrow [\text{SID}]$, $\downarrow [\text{Na}^+]$	$\uparrow [\text{SID}]$, $\uparrow [\text{Na}^+]$
b. Imbalance of strong ions		
i. Chloride excess/deficit	$\downarrow [\text{SID}]$, $\uparrow [\text{Cl}^-]$	$\uparrow [\text{SID}]$, $\downarrow [\text{Cl}^-]$
ii. Unidentified anion excess	$\downarrow [\text{SID}]$, $\uparrow [\text{SIG}]$	–
2. Nonvolatile weak acids		
a. Serum albumin	$\uparrow [\text{Alb}]$	$\downarrow [\text{Alb}]$
b. Inorganic phosphate	$\uparrow [\text{P}_i]$	$\downarrow [\text{P}_i]^c$

Adapted with permission from Fencel and Leith [177]

^aChanges in acid–base balance are controlled by changes in three independent variables – PaCO_2 , the strong ion difference, and total weak acids. As such, these disorders may be classified on the basis of their underlying cause or causes. Assessment of these three variables can explain even complex acid–base disorders

^bDiscerned by abnormal $[\text{Na}^+]$

^cBecause inorganic phosphate concentrations are normally low (≈ 1 mmol/L), hypophosphatemia has a negligible effect on acid–base balance

Alb plasma albumin concentration, $[\text{P}_i]$ plasma inorganic phosphate concentration, $[\text{SID}]$, difference between the sums of all the strong (fully dissociated, chemically nonreacting) cations (Na^+ , K^+ , Ca^{2+} , Mg^{2+}) and all the strong anions (Cl^- and other strong anions), $[\text{SIG}]$ plasma concentration of unidentified strong anions

the $[\text{Alb}^-] + [\text{Pi}^-]$. *The central tenet of the strong ion approach is that neither $[\text{H}^+]$ nor HCO_3^- can change without a change in one or more of these three independent variables.* Neither H^+ nor HCO_3^- is a strong ion. Strong ions cannot be created or destroyed to satisfy electrical neutrality, but hydrogen ions can be generated or consumed by changes in water dissociation [178]. Likewise, bicarbonate production or consumption is a result of changes in the three independent variables. Thus, the “classic” approach of looking at HCO_3^- is in a sense backward, in that we are examining the end result rather than the underlying cause of the disturbance. Acid–base disturbances may be classified according to the underlying change in these three independent variables (Table 4).

Fig. 1 Electroneutrality must be maintained in blood plasma; thus, the sum of positive charges must equal the sum of negative charges. Hydroxyl, carbonate, and protons are not shown because their concentrations are in the nanomolar to micromolar range. [SIG] represents unidentified strong anions (lactate, sulfate, keto acids, others). [SID], strong ion difference (Adapted from Fencel et al. [155])

Figure 1 demonstrates that [SID] is equivalent to the following:

$$[\text{SID}] = [\text{HCO}_3^-] + 0.28 \times [\text{Alb}^-, \text{g/L}] + 1.8 \times [\text{Pi}, \text{mmol/L}] \quad (7)$$

$[\text{HCO}_3^-]$ is obtained from arterial blood gas measurements, and the effects of albumin (g/L) and inorganic phosphate (mmol/L) are based on their direct measurement in serum. This formula is a simplification and uses factors of 0.28 and 1.8 to correct for the actual charge (in mEq) provided by albumin and inorganic phosphates. If your laboratory provides [Pi] in mg/dL, the factor for [Pi] is 0.6 rather than 1.8.

The strong ion gap [SIG], sometimes expressed as $[\text{XA}^-]$, is comparable to the anion gap in that it consists of strong anions other than Cl^- (lactate, ketoacids, and other organic anions such as toxic metabolites or sulfate), some of which are not readily measured in plasma. [SIG] is thus derived as

$$[\text{SIG}] = [\text{Na}^+] + [\text{K}^+] + [\text{Ca}^{2+}] + [\text{Mg}^{2+}] - [\text{Cl}^-] - [\text{SID}] \quad (8)$$

where [SID] is obtained from (Eq. 7). Water excess or deficit, determined on the basis of an abnormal $[\text{Na}^+]$, will alter $[\text{Cl}^-]$ and [SIG], both of which must be corrected:

$$[\text{Cl}^-]_{\text{corrected}} = [\text{Cl}^-]_{\text{observed}} \times ([\text{Na}^+]_{\text{normal}} / [\text{Na}^+]_{\text{observed}}) \quad (9)$$

Correction of chloride allows one to determine the plasma excess or deficit in chloride.

$$[\text{SIG}]_{\text{corrected}} = [\text{SIG}]_{\text{calculated}} \times ([\text{Na}^+]_{\text{normal}} / [\text{Na}^+]_{\text{observed}}) \quad (10)$$

Although this series of steps is a bit more demanding in time and cost than is the calculation

of AG, it allows recognition of complex acid–base disturbances that might be missed by simple examination of BE or AG [155]. Through Monte Carlo simulation, Antsey estimated the 95% confidence interval of normal [SIG] to be 3.9 ± 6.4 mEq/L [179]. Gunnerson and colleagues have shown that the [SIG] is substantially higher in stable ICU patients compared with healthy controls, possibly representing occult acid–base disorders or simply metabolic differences among the critically ill. In this small study of 15 healthy adults and 15 stable adult patients just before ICU discharge, the mean [SIG] was 1.4 ± 1.8 mEq/L versus 5.1 ± 2.9 mEq/L, respectively [180]. Like the anion gap, it appears the [SIG] varies from one laboratory to another and from one instrument to another, so that local norms must be established.

There are now several approaches to using quantitative acid–base chemistry clinically. In the first approach, one calculates the strong ion gap [SIG], which, similar to the AG, identifies the presence of unmeasured anions. This multi-equation approach has been criticized as too complex for the bedside such that simplified equations have been developed. Examples of these will follow. The second approach provides corrections to BE based on strong ion theory. Each approach has been shown to provide advantages over the use of the classic AG and BE.

Fencel and colleagues [155] compared the Stewart method to classic methodology (calculation of the anion gap and base excess) in a study involving nine healthy subjects ([SIG] mean \pm S. D. = 8 ± 2) and 152 intensive care unit patients. 96% of patients had serum albumin concentrations less than or equal to three standard deviations below the mean of the control subjects. In 20 and 22 patients, respectively, the base excess and plasma bicarbonate were normal. The Stewart method detected complex acid–base disturbances among many of these, in some cases grave. The authors conclusively demonstrated that reliance on the AG (particularly if not corrected for albumin) or BE results in false interpretation of the acid–base status of critically ill patients. The strong ion approach, though requiring a few more direct laboratory measurements, is comprehensive and thus more sensitive.

Durward et al. obtained arterial blood samples on admission and at 24 h in 85 children undergoing surgery for congenital heart disease. An elevated strong ion gap (>3 mEq/L) was present in 41% of children on admission and 52% at 24 h. Both the strong ion gap and lactate increased with surgical complexity. [SIG] was superior to lactate in predicting mortality [181].

Moviat et al. conducted a prospective, observational multicenter study in Dutch ICU patients. 137 of 312 consecutive patients (44%) who had normal pH, normal base excess, and normal PaCO₂ underwent arterial blood sampling. Strong ion gap was calculated from three consecutive arterial blood samples. These patients were found to have mixed acid–base disorders due to hyperchloremia and hypoalbuminemia, in spite of normal blood gas parameters [182].

Zheng and colleagues [183] studied 78 patients with metabolic acidosis with or without acute kidney injury (AKI). They analyzed physicochemical parameters at 24 and 72 h, at 1 week, 1 month, and 3 months on survival after AKI. Mortality was higher in AKI group with higher anion gaps and strong ion gaps. The AG was strongly associated with mortality at 1 and 3 months after acute kidney injury. However, an elevated [SIG] most strongly predicted mortality at 24 h, 72 h, 1 week, 1 month, and 3 months post acute kidney injury.

Applying Strong Ion Theory to the Base Excess

The corrected base excess approach to using clinical quantitative acid–base chemistry is illustrated by Balasubramanyan and colleagues [174]. They used three equations of Fencel and Leith [177] to calculate a corrected BE that takes into account the fact that free water, changes in chloride concentration, and albumin all affect BE. First, the effect on BE caused by free water (BE_{fw}) is calculated as

$$BE_{fw} = 0.3 \times (\{Na^+\} - 140) \quad (11)$$

Changes in BE accounted for by chloride are calculated as

$$BE_{Cl} = 102 - Cl_{corr}^- \quad (12)$$

where $\text{Cl}^-_{\text{corr}}$ is the corrected chloride: $\text{Cl}^- \times 140/\text{Na}^+$. Finally, the effect of albumin on BE (BE_{alb}) is calculated as

$$\text{BE}_{\text{alb}} = 3.4 \times (4.5 - \text{albumin}) \quad (13)$$

where albumin is reported in grams per deciliter.

The “classic” BE, as calculated from plasma bicarbonate, is really the sum of these three components plus a component attributable to unmeasured anions, BE_{ua} :

$$\text{BE} = \text{BE}_{\text{fw}} + \text{BE}_{\text{Cl}} + \text{BE}_{\text{alb}} + \text{BE}_{\text{ua}} \quad (14)$$

If one subtracts the first three from reported BE, one obtains BE_{ua} or BE caused by unmeasured anions:

$$\text{BE}_{\text{ua}} = \text{BE} - (\text{BE}_{\text{fw}} + \text{BE}_{\text{Cl}} + \text{BE}_{\text{alb}}) \quad (15)$$

In his study of 255 children in whom arterial blood gases, electrolytes, and albumin were measured simultaneously, Balasubramanyan demonstrated that BE_{ua} predicts increases in plasma lactate concentration better than BE and, furthermore, that it is a better predictor of mortality than either BE or the lactate concentration [174].

Story et al. [184] further simplified the FencI–Stewart methodology based on the premise that a change in the sodium-chloride component of the [SID] will change the base excess directly. Assuming a normal median sodium of 140 mEq/L and a normal median chloride of 102 mEq/L, the median difference is 38 mmol/L. The simplified version of the equation for sodium minus chloride effect on base excess is thus

$$\begin{aligned} \text{Sodium} - \text{chloride effect (mEq/L)} \\ = [\text{Na}^+] - [\text{Cl}^-] - 38 \end{aligned} \quad (16)$$

The albumin likewise has a direct effect on the base excess as the principal contributor to plasma total weak acid concentration. The simplified FencI–Stewart equation for albumin effect is as follows:

$$\begin{aligned} \text{Albumin effect (mEq/L)} \\ = 0.25 \times [42 - \text{albumin (g/L)}] \end{aligned} \quad (17)$$

This was tested prospectively in a non-randomized ICU study of 300 patient samples. In the samples, they compared the agreement between the more complex FencI–Stewart equations and their simplified versions using Bland–Altman analyses. They concluded that the simplified equations agreed well with the more complex equations. The authors proposed analysis of blood gases using the following four steps: (1) obtain standard base excess (mmol/L) from a blood gas machine; (2) calculate sodium-chloride effect (mEq/L) = $[\text{Na}^+] - [\text{Cl}^-] - 38$; (3) calculate albumin effect (mEq/L) = $0.25 \times [42 - \text{albumin (g/L)}]$; and (4) calculate unmeasured ion effect:

$$\begin{aligned} \text{Unmeasured ion effect (mEq/L)} \\ = \text{standard base excess} - \text{sodium} \\ - \text{chloride effect} - \text{albumin effect.} \end{aligned} \quad (18)$$

Employing these four steps, Ahmed and colleagues performed a randomized, prospective, interventional trial among 300 patients with “abdominal sepsis.” Patients were randomized to receive 20 mL/kg of either normal saline or Ringers lactate over 30 min. Patients in the normal saline arm had a significant drop in pH and base excess, whereas Ringers lactate patients did not. See Fig. 2. This was largely explained by the sodium-chloride effect on base excess. Dilution of serum albumin caused a partial correction of acidosis, creating a metabolic alkalosis. This mixed acid-based disorder would not have been recognized by the standard base excess approach or the anion gap approach but was detected by the FencI–Stewart method [185].

The studies of Balasubramanyan [174], FencI [155], and their colleagues provide evidence that critical care patients warrant an aggressive evaluation of acid–base status.

Osmol Gap

Osmolality is an expression of the number of particles in a given weight of solvent. Thus, each molecule of a substance, regardless of its molecular weight, contributes exactly the same as a

Fig. 2 Infusion of electrolyte solutions of varying SID will, according to the strong ion theory, variably alter the pH, base excess, and the concentrations of the strong ions themselves. These panels represent the effects of

infusion of 20 ml/kg of either normal saline (NS) or Ringer's lactate (RL) over 30 min. NS has an [SID] of 0 mmol/L ($[\text{Na}^+] - [\text{Cl}^-] = 154 - 154 = 0$ mmol/L), whereas RL has an SID of 28 mmol/L ($[\text{Na}^+] + [\text{K}^+] +$

molecule of another substance to osmolality. The vast majority of circulating osmols consist of sodium (and its associated anions), glucose, and urea. The presence of unanticipated osmols (osmol gap) is a potentially useful signal of the presence of a toxic alcohol. The true utility of the osmol gap in poisoned patients has been questioned, perhaps unfairly, on the basis of poor sensitivity [186]. However, in true clinical circumstances, the sensitivity of the osmol gap for “toxic alcohol” poisoning is 90% [187]. The osmol gap is calculated as

$$\text{OG} = \text{MO} - \text{CO} \quad (19)$$

where MO is the measured osmolality and CO the calculated (anticipated) osmolality. The small difference between osmolality and osmolality is ignored in the calculation of the osmol gap. There are normally a limited number of unmeasured osmols, so a small gap is expected. In the context of a poisoned patient, the OG is most commonly measured in an attempt to determine whether substantial concentrations of circulating exogenous osmols are present. Generally, the presence of excess measured osmols in a poisoned patient will be due to alcohols or glycols, such as ethanol, methanol, isopropanol, ethylene glycol, or propylene glycol, the last often present because of its widespread use in therapeutically administered medications. Since alcohols are volatile, MO for them should be determined by freezing-point depression to ensure that they are not liberated during determination of osmolality. This is not as much of a concern with glycols. The relative contributions of several molecules of interest to MO are indicated in Table 5. It should be

emphasized that the figures in this table are theoretical and should be used only as a rough guide to expected changes in osmolality or, conversely, plasma concentration. Osmolality is measured in mOsm/kg H₂O. Numerous formulas have been used for calculation of this gap, and one popular formula for the predicted serum osmolality, proposed by Dorwart and Chalmers, [159] follows:

$$\begin{aligned} &\text{Standard International [SI] units} \\ \text{CO} &= 1.86 [\text{Na}^+] + [\text{Glucose}] + [\text{BUN}] + 9, \end{aligned} \quad (20a)$$

where concentrations of sodium, glucose, and blood urea nitrogen (BUN) are expressed in mmol/L.

$$\begin{aligned} &\text{Mass Units} \\ \text{CO} &= 1.86 [\text{Na}^+] + [\text{Glucose}/18] \\ &\quad + [\text{BUN}/2.8] + 9, \end{aligned} \quad (20b)$$

where sodium is expressed in mmol/L and glucose and urea in mg/dL [159].

Purssell and colleagues [189] derived an osmol gap formula using linear regression with the blood ethanol concentration taken into account and then validated it in convenience samples from 128 patients. This formula is based on that of Mahon et al. [190], who used a multiplier of 2 for Na⁺ rather than 1.86. Purssell added a correction factor of 1.25 in SI units for the contribution to osmolality by ethanol. Given the frequency with which ethanol is found in poisoned patients, its presence should be confirmed and included in the calculation. Thus, adding the Purssell ethanol correction factor,

Fig. 2 (continued) $[\text{Ca}^{2+}] - [\text{Cl}^-] = 130 + 4 + 3 - 109 = 28 \text{ mmol/L}$. **Panel A.** Changes in pH following infusion of normal saline or Ringer’s lactate. **Panel B.** Changes in serum base excess, sodium, chloride, and anion gap following infusion of normal saline or Ringer’s lactate. **Panel C.** Changes in standard base excess, sodium minus chloride effect, albumin effect, and unmeasured anion effect on base excess following infusion of normal saline or Ringer’s lactate (Adapted from Ahmed et al. [185])

one arrives at a formula for CO, corrected for measured blood ethanol (CO_{corrected}):

SI units
$$\text{CO}_{\text{corrected}} = 2\{\text{Na}^+\} + \{\text{Glucose}\} + \{\text{BUN}\} - 1.25 \times \{\text{Ethanol}\}$$

(21a)

If mass units (mg/dL) are used for the latter three, the following formula is used:

Mass Units
$$\text{CO}_{\text{corrected}} = 2\{\text{Na}^+\} + \{\text{Glucose}\}/18 + \{\text{BUN}\}/2.8 - \{\text{Ethanol}\}/3.7$$

(21b)

Two more recent studies have studied the effect of ethanol on the osmol gap [191, 192]. Carstairs and colleagues gave ten healthy volunteers up to 140 mL 100% ethanol in sugar-free soda (n = 8) or plain sugar-free soda (n = 2). The Dorwart formula was used. The osmol gap was divided by the blood ethanol to determine the mean coefficient of ethanol’s contribution to serum osmolality, yielding 4.25 (95% CI, 4.13–4.38). This divisor is smaller than that predicted by molecular weight of ethanol, indicating that it contributes

more to total osmolality than predicted for an ideal solute [191]. The study has been criticized for proposing a mean coefficient when the underlying individual subjects had coefficients that were substantially inconsistent [193]. In a much larger study of 603 emergency department patients, Garrard and colleagues retrospectively reviewed patients who had concurrent ethanol, basic metabolic panel, and measured serum osmolality results available [192]. The median ethanol concentration was 166 mg/dL (36 mmol/L). The mean osmol gap was 47, with a significant proportional relationship between ethanol and osmol gap. The authors concluded that the contribution of ethanol to the osmol gap is defined by the ethanol concentration (mg/dL)/4.0 [192].

Dozens of formulas of varying performance have been proposed for the plasma osmolality calculation. Not surprisingly skepticism about the value of the osmolal gap as a predictive tool for the presence of toxic alcohols has arisen [186]. Nonetheless, many hospitals do not have access to immediate confirmation for the presence and quantity of toxic alcohols in the blood. They thus depend on the anion and osmol gaps for determining the likelihood of a toxic alcohol exposure.

Khajuria and Krahn [188], in an effort to derive a formula that can be used in normal patients, as well as in those who are hyperglycemic and/or intoxicated, performed a series of *in vitro* experiments and tested several formulas for the calculated osmol gap. They demonstrated that glucose and alcohols don't accurately predict osmolality on the basis of their molecular weights alone. The experiments demonstrated the need for correction factors for glucose, ethanol, methanol, and ethylene glycol of 1.15, 1.20, 1.07, and 1.00, respectively, in order to accurately predict osmolality. The authors then tested two formulas against data from 37 healthy volunteers (without ethanol) and 129 emergency department patients with mean ethanol concentrations of 41.5 ± 27.0 mmol/L. Both formulas predicted osmolality well, in the presence or absence of ethanol. One of the two formulas, a modification of the Dorwart formula [159], with potassium added follows:

$$\begin{aligned} \text{SI units} \\ \text{CO} &= 1.86[\text{Na}^+ + \text{K}^+] + 1.15[\text{Glu}] \\ &+ [\text{Urea}] + 1.2[\text{Ethanol}] + 14 \end{aligned} \quad (22a)$$

This formula yielded a mean osmol gap of 0.77 ± 3.80 mOsm/kg in healthy volunteers (without ethanol). The mean osmol gap in patients with ethanol present was -0.2 ± 5.00 mOsm/kg, with a reference interval of -8.04 – 6.50 mOsm/kg [188], substantially narrower than that reported by Hoffman and colleagues (-5 – 15 mOsm/kg, using a different formula) [186]. This formula and that of Siervo (see below) utilize urea in SI units rather than BUN. However, there is 1 mmol of nitrogen in 1 mmol of urea, so the conversion is the same as usual if BUN is employed (i.e., divide by 2.8 to obtain mmol/L from mg/dL):

$$\begin{aligned} \text{Mass Units} \\ \text{CO} &= 1.86[\text{Na}^+ + \text{K}^+] + 1.15[\text{Glu}/18] \\ &+ [\text{BUN}/2.8] + 1.2[\text{Ethanol}/4.6] + 14 \end{aligned} \quad (22b)$$

One notes that the correction factor for ethanol in this case resolves to $4.6/1.2 = 3.8$, almost precisely the correction factor proposed by Pursell [189].

Siervo and colleagues [194] subsequently compared 38 predictive equations, including the Khajuria formula (minus the ethanol correction), in a group of 186 frail older people with and without diabetes. They found four equations which showed reasonable agreement with measured osmolality, but that the formula with narrowest limits of agreement was the following:

$$\text{CO} = 1.86[\text{Na}^+ + \text{K}^+] + 1.15[\text{Glu}] + [\text{Urea}] + 14.$$

One immediately notes that this is the same formula as that of Khajuria (Eq. 22a) minus the correction for ethanol.

Martin-Calderon and colleagues [195] independently compared 14 calculated osmolality equations, comparing goodness of fit of the calculation with osmolality measured by freezing-point depression among 146 healthy volunteers (96 males/50 females). They warned that the original Dorwart-Chalmer equation should not be used for osmolality calculations. Like Siervo, they did not include ethanol in their calculations. The best fit was obtained by the same equation adjusted for use of mass units:

$$\begin{aligned} \text{CO} &= 1.86[\text{Na}^+ + \text{K}^+] + 1.15[\text{Glu}/18] \\ &+ [\text{BUN}/2.8] * + 14 \end{aligned}$$

* BUN/2.8 was substituted for urea/6 for use in the USA, where measurement of urea is uncommon. Thus, while prospective confirmation of its validity in a wide variety of patients with normal values, hyperglycemia, elevated blood ethanol, and/or toxic alcohols is needed, this formula (adding the correction for ethanol) clearly looks promising.

One other issue of importance to the calculation of the osmol gap is that of "pseudohyponatremia" associated with hyperglycemia. Pseudohyponatremia is an accurate description of the volume exclusion effect of very elevated triglycerides or protein when sodium is measured by indirect methods. The move to specific ion electrodes has largely eliminated this issue. The decrease in sodium seen with hyperglycemia is not pseudohyponatremia, but rather a shift of water from the intracellular space to the plasma induced by the osmotic effect of glucose, such that the sodium in the vascular compartment is indeed

decreased by dilution. The specific ion electrode for sodium provides accurate measurements even in the presence of elevated glucose; thus, there is no reason to “correct” the sodium for elevated glucose in calculating the osmol gap [196].

So, what is one to do with these different equations for calculated osmols? First, inquire from your laboratory whether they have determined the normal osmol gap in your patient population. As Pursell warns, the calculation of the osmolal gap at the bedside without knowledge of how the calculation works in that environment is poor practice and subject to serious error [189]. Of the published equations, the Khajuria (Eqs. 22a and 22b) appear to offer very close correlation with measured osmols. In the end, it is important to remember that assuming the presence or absence of a toxic alcohol on the basis of the osmol gap, regardless of formula, is not ideal. It is imperative to understand that the range of “normal” osmol gaps will vary significantly, depending on the calculation chosen and on laboratory equipment used for the analysis. The osmol gap appears to be most reliable when it exceeds 25 mOsm/kg [197], although a more recent paper reports excellent sensitivity down to 10 mOsm/kg [187]. Because of variations in the results (and normal values) obtained depending on the formula used, the relatively small number of osmols produced by a toxic concentration of ethylene glycol (a blood concentration of 25 mg/dL [4 mmol/L] is equivalent to only ≈ 4 mOsm/kg see Table 5), and the possibility of missing even *severe* very early or late manifestations of ethylene glycol or methanol toxicity, the osmol gap should be interpreted with caution. Small or absent anion or osmol gaps may be obtained after severe toxic alcohol poisoning, depending on the extent of absorption and metabolism that have taken place since the ingestion. Therefore, both anion and osmol gaps must be viewed with prudence and do not completely rule out such poisonings. If any clinical suspicion exists, a direct measurement of the possible offending alcohols or glycols should be obtained and strong consideration given to initiation of blockade of alcohol dehydrogenase (ADH). When the osmol gap is elevated in the case of methanol poisoning, the osmol gap may be

followed to assess treatment progress. Jacobsen and colleagues have reported on 28 patients from a recent methanol outbreak, in whom the osmol gap predicted in a linear fashion the methanol concentration, with a correlation coefficient of 0.94 [198]. This same group demonstrated good correlation between serum methanol and osmol gaps during hemodialysis, concluding that, in the absence of serum methanol analyses, the osmol gap is useful to assess indication for and duration of dialysis in methanol poisoned patients [199].

An unvalidated algorithm in which the various gaps are used for evaluation of acid–base disorders is presented in Fig. 3. Suggestions for use of the anion and delta gaps are found in Figs. 4 and 5, respectively. A side-by-side comparison of the Stewart and modified anion gap–base excess methodologies is found in Fig. 6.

Arterial Blood Gases

Interpretation of arterial blood gases in a poisoned patient does not differ significantly from that in other patients and is therefore not discussed in detail here. It is worthwhile, however, to note that according to the strong ion theory, the change in pH induced by a change in PaCO_2 will vary depending on $[\text{SID}]$ and A_{TOT} , thus indicating that PaCO_2 is important not only in respiratory acidosis but also in metabolic acidosis and reinforcing the importance of evaluation of all three independent variables [176]. The compensation formulas for simple acid–base disorders proposed by Narins and Emmett [200] are provided in Table 6. The caveats discussed above with regard to “standard” bicarbonate hold.

Treatment of Acid–Base Disorders

The *sine qua non* of therapy for acid–base disorders is correction of the underlying cause of the disorder. Attention to the patency of the airway and adequacy of ventilation and oxygenation cannot be overemphasized.

In terms of metabolic derangements, the strong ion theory significantly simplifies the task of

Fig. 3 An unvalidated algorithm (level of evidence III) for the evaluation of acid-base disorders based on clinical suspicion of a disorder or patient acuity. While simple acid-base evaluation, using classic laboratory studies and calculation of “gaps,” may suffice where suspicion of acid-base derangements and acuity is low, quantitative “strong ion” analysis is indicated where there is high suspicion of acid-base disorder or high acuity. Failure to clarify the etiology of the disorder with simple gaps and

ABG analysis should also indicate the need for quantitative acid-base analysis. See text and Fig. 6 for details on calculation. Abbreviations: *ABG* arterial blood gas, *AG* anion gap, *ALB*⁻ serum albumin, *AMS* altered mental status, *BE* base excess, *LOE* level of evidence, *Pi* inorganic phosphate, *[SIG]* strong ion gap. correction. A careful evaluation of strong ions will determine the need for electrolyte replacement, so reflexive administration of large volumes of solutions that alter *[SID]*, such as sodium chloride, is avoided in the treatment of metabolic acidosis. Hypoperfusion persisting in spite of correction of vascular water and electrolyte deficits may require the use of vasoactive substances. It must be appreciated that their use may often worsen acidosis via the production of lactate, so careful attention to the risk-benefit ratio of their use is of utmost clinical interest [201, 202].

Since the advent of the Stewart approach, increasing attention has been directed at correction of strong ion differences through the use of

various crystalloid solutions. Morgan and colleagues studied the relationship between the strong ion difference of a diluting crystalloid and its acid-base effects on *in vitro* blood dilution [203]. They tested three solutions of varying chloride content (120, 110, and 100 mmol/L (*[SID]* equals 20, 30, and 40 mEq/L respectively), as well as 0.9% saline (*[SID]* equals 0) and Hartmann solution (*[SID]* equals -4 mEq/L). With the exception of the solution of 40 mEq/L *[SID]*, for which *[SID]* did not change, plasma *[SID]* decreased during hemodilution. For solutions with higher *[SID]*, base excess increased during hemodilution. The relationship between hemoglobin concentration and both plasma *[SID]* and a

Fig. 4 Evaluation of the anion gap (AG). *AG is calculated as $[\text{Na}^+] - ([\text{Cl}^-] + [\text{HCO}_3^-])$. The normal range of AG is 3–11 mmol/L but will vary according to individual hospital laboratories. **Correction for hypoalbuminemia: $\text{AG observed} + 0.25 \times ([\text{Albumin, nL}] - [\text{Albumin observed}]) = \text{AG corrected}$, where normal albumin is considered to be 45 g/L. ***Correction for

hyperphosphatemia: $\text{AG observed} - 0.32 \times ([\text{Phosphate observed}] - [\text{Phosphate, nL}]) = \text{AG corrected}$, where the upper normal phosphate level is considered to be 5 mg/dL. If phosphate is reported in mmol/L, simply drop the multiplier of 0.32. ABG, arterial blood gases; [SIG], strong ion gap. Level of evidence: Corrected anion gap-II-2

whole blood base excess were linear. Linear regression revealed the [SID] of crystalloid producing a 0 base excess/hemoglobin concentration slope during blood dilution (in other words no acid–base change) was 23.7 mEq/L. This same group demonstrated in rats undergoing normovolemic hemodilution that there is a linear relationship between the crystalloid [SID] and the postdilutional metabolic acid–base status [204]. The [SID] of a crystalloid balance for normovolemic hemodilution is 24 mEq/L, identical to the standard bicarbonate.

Omron and Omron performed clinical simulations of modeled acid–base and fluid compartment parameters in a 70 kg test participant at standard physiologic state [205]. Comparing simulated infusions of up to 10 L of normal saline ([SID] equals 0), Ringers lactate ([SID] equals 28), Plasma-Lyte 148 ([SID] = 50), half normal saline +75 mEq sodium HCO_3^- ([SID] = 75) and 0.15 mole/L sodium ([SID] = 150) with a

hypothetical crystalloid solution of [SID] = 24.5 mEq/L, the authors demonstrated that a crystalloid [SID] equivalent to standard-state actual HCO_3^- (24.5 mEq/L) results in a neutral metabolic acid–base status or standardized base excess approximately equal to 0 mEq/L for infusions up to 10 L. The larger the infused volume, the greater the displacement of SBE from 0 mEq/L when crystalloid [SID] and actual HCO_3^- are discordant. The lower the [SID] relative to actual HCO_3^- , the greater the standard base deficit; the greater the crystalloid [SID] relative to actual HCO_3^- , the greater the SBE. A 1 L normal saline infusion resulted in metabolic acidosis, whereas the same infusion of Ringers lactate resulted in metabolic alkalosis.

In 2013, Morgan [123] reviewed the subject of the “balanced” crystalloid in the context of quantitative acid–base chemistry. Noting that the [SID] of isotonic saline is 0 (equal concentrations of sodium and chloride), Morgan makes the case

Fig. 5 Evaluation of the delta gap. *The delta gap is calculated as $\Delta\text{gap} = \Delta\text{AG} - \Delta\text{HCO}_3^-$, where ΔAG = observed AG – the upper normal limit of the AG and ΔHCO_3^- = lower normal HCO_3^- – observed HCO_3^- . The normal range for the delta gap is 0 ± 6 . **Albert

formula: Expected $\text{PaCO}_2 = 1.5 [\text{HCO}_3^-] + 8 + 2$.

(Adapted from Wrenn [141]). Level of evidence: Delta gap-III

that administration of large volumes of saline over a relatively short period of time forces reductions in [SID], leading to hyperchloremic metabolic acidosis, while at the same time reducing Atot through dilution of plasma proteins and phosphate, which gives rise to metabolic alkalosis. The net result however is metabolic acidosis. Admittedly, saline-induced acidosis is relatively mild to moderate. Nonetheless, he underscores that there are data suggesting that hyperchloremic metabolic acidosis is pro-inflammatory, causing multiorgan dysfunction. He reminds us that reduced chloride exposure may lessen kidney injury with a possible mortality benefit [206]. To achieve exact balance from an acid–base perspective, it is sufficient to reduce the strong ion difference to 24 mEq/L. This can be done by replacing chloride in an isotonic saline solution with HCO_3^- or a substitute such as acetate. He points out that Ringer’s acetate solution is as close to a balanced solution that exists currently, both from acid–base and tonicity perspectives. He suggests that a large, randomized clinical trial is necessary to

establish definitively the benefits of using a balanced crystalloid solution [123].

Ragunathan and colleagues carried out a retrospective cohort study of patients admitted with sepsis, comparing those who received only “no-balanced fluids” (i.e., isotonic saline with or without dextrose 5% [SID] = 0) against patients who received some (widely variable) quantity of “balanced” solutions such as Ringers lactate in 53,448 patients among 360 US hospitals [207]. While the patients treated with balanced fluids were younger and less likely to have heart disease or chronic renal failure, they were more likely to receive mechanical ventilation, invasive monitoring, colloids, steroids, and larger crystalloid volumes. The authors then applied propensity matching to arrive at two comparison groups of 3,396 matched subjects. Receipt of balanced fluids was associated with lower in-hospital mortality (19.6% vs. 22.8%) with mortality progressively decreasing among patients receiving larger proportions of balanced fluids [207]. While these findings are of interest, there are clearly methodological issues.

Fig. 6 Evaluation of patients with perceived complex acid–base disorders. Both Stewart physicochemical methods and modifications of the anion gap and base excess methodology have been proposed in recent years. The choice of methodology remains controversial, so multiple methods of acid–base analysis are provided here.

Abbreviations: Alb^- albumin, ABG arterial blood gas, AG_c corrected anion gap, BUN blood urea nitrogen, [SID] strong ion difference, [SIG] strong ion gap, UA unmeasured anions. Level of evidence: Corrected anion gap-II-2; Delta gap-III; [SIG]-I; BE corrected-II-1

Thus, a large randomized controlled trial of well-defined balanced versus unbalanced fluids is clearly needed.

The comparison of Ringers lactate to normal saline and abdominal sepsis patients by Ahmed and colleagues has already been cited. Figure 2 demonstrates significant differences in pH and base excess induced by relatively modest (20 mL/kg) infusion volumes of 0 [SID] solutions such as normal saline.

The specific (i.e., other than supportive) treatment of acid–base disorders remains controversial. For many years, the cornerstone of treatment of metabolic acidosis, with the exception of DKA, was the administration of bicarbonate, sometimes in very large quantities. Correction of abnormal pH (excess H^+) via administration of bicarbonate

appears logical on the surface. However, Graf and colleagues [208] pointed out evidence that administration of bicarbonate may actually worsen intracellular acidosis, which led to proposals by some that we should “ban bicarbonate” in the treatment of acidosis [209]. Whether this rapid swing of the pendulum in the opposite direction was warranted depends on the belief that all metabolic acidosis is alike and should therefore be treated similarly. One might question, however, whether the acidosis produced by metabolic conversion of methanol is equivalent to the lactic acidosis produced in septic shock. Kellum has pointed out that when treatment is based on [SID], the need for bicarbonate therapy becomes clear [175]. If the disorder involved is characterized by decreased or normal sodium, administration of sodium in the

Table 6 Formulas for expected compensation in simple acid–base disorders

Disorder	Formula
Metabolic acidosis	Change in $\text{PaCO}_2 = 1.2 \times \text{change in } \text{HCO}_3^-$
Metabolic alkalosis	Change in $\text{PaCO}_2 = 0.6 \times \text{change in } \text{HCO}_3^-$
Acute respiratory acidosis	Change in $\text{HCO}_3^- = 0.1 \times \text{change in } \text{PaCO}_2$
Acute respiratory alkalosis	Change in $\text{HCO}_3^- = 0.2 \times \text{change in } \text{PaCO}_2$
Chronic respiratory acidosis	Change in $\text{HCO}_3^- = 0.35 \times \text{change in } \text{PaCO}_2$
Chronic respiratory alkalosis	Change in $\text{HCO}_3^- = 0.5 \times \text{change in } \text{PaCO}_2$

Adapted from Narins and Emmett [200]

Changes represent differences from normal values for PaCO_2 (40 mmHg) and HCO_3^- (24 mEq/L). See text for cautions regarding standard HCO_3^-

form of bicarbonate may in fact be warranted. However, it is in reality the sodium concentration (the strong ion) that is being addressed. If one accepts the Stewart theory, bicarbonate will actually be determined by the three independent variables (strong ions, PaCO_2 , and weak acids/salts). Only by increasing sodium relative to chloride can sodium bicarbonate “repair” metabolic acidosis. Thus, when sodium is already increased, there is no role for bicarbonate therapy [175]. Other considerations make the use of sodium bicarbonate potentially appropriate in metabolic acidosis of toxic origin. Alkalinization of the urine has a demonstrated beneficial effect on the distribution of salicylates and barbiturates by hastening elimination and diminishing CNS penetration. Sodium administration (as bicarbonate or hypertonic saline) appears to be effective as well in the treatment of cyclic antidepressant-related dysrhythmias, which may be associated with metabolic acidosis [210–212]. In summary, although bicarbonate should no longer be viewed as the “universal antidote” for metabolic acidosis, its use should not be summarily abandoned in all cases of acidosis. Kraut and Madias have recently provided recommendations for calculation of

bicarbonate requirements in severe lactic acidosis ($\text{pH} \leq 7.10$), diabetic ketoacidosis ($\text{pH} \leq 7.0$), and non-gap metabolic acidosis ($\text{pH} \leq 7.20$) when attempts at correcting the underlying disorder have been unsuccessful:

$$\begin{aligned} \text{Bicarbonate requirement} &= \text{desired } [\text{HCO}_3^-] - \\ &\quad \text{present serum } [\text{HCO}_3^-] \times \text{bicarbonate space,} \\ &\quad \text{where bicarbonate space} = [0.4 + (2.6/\text{HCO}_3^-)] \\ &\quad \times \text{body weight (kg)} \end{aligned} \quad (23)$$

The authors further recommend that, in order to minimize potential complications of bicarbonate administration, therapy should be initiated based on calculation using bicarbonate space of 50% body weight (kg); if this is not successful in achieving desired serum $[\text{HCO}_3^-]$, administer larger quantities of bicarbonate based on bicarbonate space calculated from the above formula [213].

The use of the strong ion approach allows us to not only recognize the often multiple underlying causes of acid–base disorders but also correct them. Hypoalbuminemia contributing to severe metabolic alkalosis may warrant replacement therapy. Chloride excess leading to acidosis may be addressed by hemofiltration or the use of a weak base such as tris(hydroxymethyl) aminomethane (THAM, or tromethamine). The presence of a strong ion gap (excess unmeasured anions) calls for therapy to reduce their production or facilitate their removal [175].

THAM has been proposed as an alternative to sodium bicarbonate, because it reduces arterial hydrogen ion concentration without producing CO_2 and penetrates cells easily, reducing intracellular acidosis [214]. Weber and colleagues studied THAM in 12 patients undergoing permissive hypercapnia for ARDS [215]. Patients who received THAM experienced less myocardial depression and lessened effects of hypercapnia on arterial pressure and mean pulmonary arterial pressure. Marfo and colleagues reported the case of a patient with severe lactic acidosis secondary to highly active antiretroviral therapy successfully treated with THAM [216]. Several studies have shown promising results in selected patient populations [217, 218], but additional studies are

needed. Kraut and Madias recommend consideration of THAM in patients with lactic acidosis, diabetic ketoacidosis, or non-gap metabolic acidosis in patients when CO_2 retention is present or incipient. They estimate THAM requirements using the following formula:

$$\begin{aligned} &0.3 \text{ M THAM requirement (in ml)} \\ &= \text{body dry weight (kg)} \\ &\times \text{base deficit (mEq/l)} \times 1.1, \end{aligned} \quad (24)$$

where base deficit = desired serum $[\text{HCO}_3^-]$ – actual serum $[\text{HCO}_3^-]$ [213].

Finally, extracorporeal treatments may be of interest in acidosis of toxic etiology [219–221]. Hemodialysis can correct not only the plasma bicarbonate (the result of the underlying disturbance in strong ion imbalance) but also some strong ion abnormalities (hyperkalemia). Furthermore, it has the capacity to remove a number of endogenous (lactate, pyruvate) and exogenous (methanol and metabolites, ethylene glycol and metabolites) compounds of low molecular weight and limited volume of distribution.

Based on admittedly limited data (mostly case reports), the Extracorporeal Treatments in Poisoning (EXTRIP) workgroup has recommended extracorporeal removal of metformin in the case of severe poisoning (plasma lactate > 20 mmol/L [180 mg/dl], $\text{pH} \leq 7.0$, shock, failure of standard support measures, and decreased level of consciousness) [222]. EXTRIP has also recently released recommendations for extracorporeal treatment for valproic acid (VPA) poisoning. Intermittent hemodialysis is recommended for valproic acid poisoning when at least one of the following criteria for severe poisoning is present: VPA concentration > 1,300 mg/L (9,000 $\mu\text{mol/L}$), the presence of cerebral edema, or shock; suggestions for extracorporeal treatment include a VPA concentration > 900 mg/L (6,250 $\mu\text{mol/L}$), coma or respiratory depression requiring mechanical ventilation, acute hyperammonemia, or $\text{pH} \leq 7.10$ [223]. Note, however, that some degree of hyperammonemia is common with even minor VPA toxicity. Thus, the hyperammonia should be significant if that is the only reason the patient is

being considered for extracorporeal drug elimination. Cessation of extracorporeal treatment (ECTR) is indicated when clinical improvement is apparent or the serum VPA concentration is between 50 and 100 mg/L (350–700 $\mu\text{mol/L}$). Intermittent hemodialysis is the preferred ECTR in VPA poisoning. If hemodialysis is not available, then intermittent hemoperfusion or continuous renal replacement therapy is an acceptable alternative. EXTRIP has recommended extracorporeal treatment for acetaminophen (APAP) poisoning in the case of mitochondrial dysfunction as reflected by early development of altered mental status and severe metabolic acidosis preceding liver failure [224]. They point out that extracorporeal treatment should be reserved for those rare situations when the efficacy of N-acetylcysteine (NAC) cannot be definitively demonstrated. Specific recommendations for extracorporeal treatment include: an APAP concentration over 1,000 mg/L (6,600 $\mu\text{mol/L}$) if NAC is not administered, signs of mitochondrial dysfunction and an APAP concentration over 700 mg/L (4,630 $\mu\text{mol/L}$) if NAC is not administered, and signs of mitochondrial dysfunction and an APAP concentration over 900 mg/L (5,960 $\mu\text{mol/L}$) if NAC is administered (level of evidence [LOE] = III). Intermittent hemodialysis (HD) is the preferred ECTR modality in APAP poisoning [LOE] = III.

Summary

Acid–base disorders in poisoned patients may be of multiple toxic and nontoxic etiologies. A careful history and physical examination are necessary to suspect the disorder, and a thorough laboratory evaluation is required to distinguish the probable etiology. Reliance on simple calculations such as anion or osmol gaps may result in errors, including missed diagnosis. A systematic approach using multiple diagnostic tools, including the quantitative (strong ion) method, will decrease the likelihood of errors. Treatment is largely supportive. Bicarbonate or THAM therapy is useful in selected cases but should be based on a quantitative analysis of acid–base derangements rather than being a rote response to abnormal

laboratory values. Hemodialysis may also be of benefit in selected patients, again relying on the patient's clinical condition as a guide to therapy.

Acknowledgment This chapter is dedicated to the memory of Professor Chantal Bismuth, whose contributions to medical toxicology are innumerable and lasting. With her sharply analytical mind, incisive wit, and charming smile, she mentored hundreds of toxicologists-in-training, challenged the status quo, and brought focus to many nebulous concepts in toxicology. She will be missed.

Lung-Damaging Toxicants

Lung-damaging toxicants may be defined as chemicals that induce pathological changes in the lung following absorption [1, 2]. The acute respiratory distress syndrome (ARDS) is a clinical syndrome which might be caused by direct damage to the respiratory cells at the alveolar level or indirectly through inflammation mediators in a severely exposed patient.

The true incidence of people being exposed to lung-damaging toxicants is unknown. The incidence that can be deduced from case reports, case series, and (inter)national registries is likely to represent only a minute fraction of the true incidence as the majority of patients do not seek medical attention. Furthermore, where medical treatment is necessary, many physicians do not inform poison information centers. Either they know how to treat such patients and do not need advice, or, more likely, they are unaware that an exposure is causing the respiratory effects.

The burden of inhalatory toxicants is unknown. However, the ubiquitous nature of these gasses (e.g., chlorine from household products, swimming pools) and its use in industry put many at risk. Due to the accidental nature of many of these intoxications, often many people are exposed simultaneously. A devastating example of such industrial exposure with numerous civilian fatalities is the infamous gas leak of Bhopal (India). In 1984, an exothermic reaction in a carbaryl producing factory plant caused the release of approximately 30 metric tons of methyl isocyanate in a densely populated area. This resulted in over 2500 deaths and 200,000 injuries [3]. Arguably, this is the largest industry evoked exposure of lung-damaging toxicants. While most of these acute inhalatory intoxications are the result of accidents, intentional exposure as a result of warfare or terrorist acts is an persisting threat (see Box 1).

In this chapter we will discuss the treatment options of patients with chemically induced ARDS.

Box 1: Warfare Use of Poisonous Gasses

A typical example of mass exposure and multiple deaths is the use of chemical gasses during warfare. Toxic fumes were used in the war between the Athenians and the Spartans in 428 BC, when the Athenians used a combination of pitch and sulfur to incapacitate their opponents. It can be assumed that during the many wars hereafter many were exposed to “toxic fumes.” However, one of the most well-known and best documented wars that used chemical gasses was the First World War. During this war, all parties used chemical gasses to injure, demoralize, and kill opponents. In 1914, irritant gasses were used (so-called tear gasses, like ethyl bromoacetate). These gasses were intended to induce irritation and thus handicap soldiers. The first lethal gas to be employed in the trenches is said to be xylyl bromide [4]. However, in the cold weather, the chemical froze and did not have the desired effect. Additionally, bromine was hard to obtain causing the Germans to switch to chlorine. This chemical gas was a by-product of the German dye manufacturing and could be produced in sufficient amounts. Chlorine is a powerful irritant and in high and prolonged exposures, it may also cause pulmonary injury. This is discussed in greater detail in ► [Chap. 100, “Irritant and Toxic Pulmonary Injuries.”](#) Although many soldiers perished in these poisonous gas attacks, chlorine was not a very effective warfare agent. Soldiers who stood on high ground and kept their exertion to a minimum often survived. Injured soldiers that lay on the ground (prolonged exposure to a dense and heavy gas) or fled in the gas clouds (exertion) were at risk of pulmonary involvement and even death. Chlorine gas is easy to detect (visible greenish clouds with a strong odor) and

(continued)

several counter measures were applied. Chlorine is moderately water soluble and covering the nose and mouth with a moist cloth was somewhat effective. This quickly developed into more sophisticated gas masks.

In 1915, phosgene gas was introduced. It was colorless and difficult to detect, making it a more effective weapon than chlorine. However, phosgene had one major drawback, it took several hours before the symptoms became manifest. Therefore, there was a delay between exposure and incapacitation of the opposing troops.

In 1917, mustard gas was introduced by the Germans. Mustard is a vesicant (meaning blister provoking) that is not extremely lethal, although in high enough doses it might be fatal. However, it was used to disable the opponents. The skin of victims of mustard gas blistered, their eyes became inflamed, and they developed emesis. Mustard caused internal and external bleeding and attacked the bronchial tubes, denuding their mucous membrane. This was extremely painful. Fatally injured victims sometimes took 4 or 5 weeks to die of mustard gas exposure [5, 6]. The combination of chlorine, phosgene, and mustard gas continued to be used throughout the First World War; however, its effectiveness diminished against well-trained and well-equipped soldiers. The use of chemical gases was widespread in subsequent wars. In 1925, a treaty was conceived banning the use (but not stockpiling) of chemical weapons. Many countries ratified this, although some countries took more than 50 years to finally agree with this prohibition.

In 1988, Iraqi Air Forces dropped chemical weapon canisters on the town of Halabja. More than 5,000 people died of the immediate attack, and another 7,000 were injured or suffered long-term sequelae [7]. The attack was said to include vesicant

mustard gas as well as several nerve agents, such as tabun, sarin, and VX (quite lethal although not producing pulmonary symptoms). However, this has been denied by other sources.

For more information, see also ► [Chaps. 135, “Nerve Agents,”](#) and ► [136, “Sulfur Mustard.”](#)

Three Types of Acute Inhalation Exposures

Several elements of the respiratory tract contribute to the protection of the respiratory system from lung-damaging toxicants and inhaled particles (e.g., smoke). In the upper respiratory tract, particles larger than 5–10 μm (microns) are trapped through turbulence in the mucosal surfaces of the nose and mouth. In the conducting airways, ciliated and mucus-secreting epithelial cells move particles upward. It is estimated that this “mucociliary escalator” can move inhaled particles up the respiratory tract at approximately 1–4 cm per hour [8]. In the more distal airways, alveolar macrophages and neutrophils play an important role. They phagocytose particles and destroy them through hydrolyses containing lysosomes. Lymphatic clearance of particles is another, less important, mechanism of pulmonary clearance. The downside of macrophage and neutrophil involvement is the potential for activation of the inflammatory cascade.

The lung parenchyma is capable of metabolizing some inhaled toxins, but this is only a minor contributor to biotransformation of inhaled toxins. The majority is either exhaled or absorbed and subsequently excreted through other mechanisms (e.g., renal or hepatic clearance).

Three fundamental parameters determine the extent of involvement of lung-damaging toxicants: water solubility, duration of exposure, and minute ventilation. Water solubility plays a significant role in determining the location of toxic inhalation injury. Clinically, three types of

Fig. 1 Three types of reactions to inhaled toxins. There are three routes by which lung-damaging toxins can cause pulmonary damage. In type I exposure, the (often hydrophilic) lung-damaging toxin does not penetrate deep into the lung and causes irritation to the upper membranes. In type II exposure, the (often lipophilic) lung-damaging

toxicant penetrates deeper into the lung and causes damage at the alveolar level. In type III exposures, the toxicant is not or only minutely damaging the lung, but the effects after exposure and absorption are exerted elsewhere in the human body

inhalation injury are described, which are related to the physical properties of the inhaled toxin [1, 2, 9]. The first type (type I) consists of inhalation of a water-soluble toxicant, which causes direct irritation to the membranes of the upper respiratory tract. The second type (type II) reflects exposure to toxicants that are poorly soluble in water, which penetrate deeper into the lungs and cause damage at the alveolar level. The third type (type III) involves a toxic agent that does not directly cause damage to the lungs, but is absorbed and causes damage elsewhere or after metabolism (Fig. 1). An alternative, but important, route of exposure to lung-damaging toxicants is through non-pulmonary absorption. This often involves absorption through the gastrointestinal tract or skin.

Type I Inhalation Injury

Generally, agents that are soluble in water (see Table 1) are easily dissolved in the mucus of the upper airways. This results in a chemical process (oxidation, reduction, or pH change) in the mucosal membranes. After cessation of the initial exposure, this chemical reaction terminates, although an inflammatory response may continue.

Symptoms occur instantly after exposure and the nose and eyes are usually also involved. The symptoms are pain in the upper airways while breathing, nasal discharge, and lacrimation. In more severe cases, dyspnea due to bronchospasm, bronchial edema, glottis edema, and increased mucus production may be present; hemoptysis and cyanosis may become manifest. Although pulmonary edema might occur after exposure to water-soluble agents, it will never be the sole manifestation.

Type II Inhalation Injury

Shortly after inhalation of poorly water-soluble compounds (see Table 1), symptoms are not usually present in the first few hours after exposure (level of evidence [LoE] grade III) [9]. Examples of agents that cause such a delayed response are listed in Table 1. Consequently, examination directly after exposure may not provide information regarding the full extent of the severity of the intoxication. Rarely, minor irritative effects in the upper airways or nausea are present but generally bronchospasm is not prominent. After several hours, depending on the concentration of the agent and the duration of exposure, ARDS may

Table 1 Classification of lung-damaging toxicants and their site of action. This is not an exhaustive list, but it does give some examples of lung-damaging agents (LDAs) causing inhalation injuries. Water-soluble toxic agents (type I exposure)
Chlorine [10]
Chloramine [11]
Ammonia [12, 13]
Anhydrides [14]
Aldehydes of lower molecular weight (acrolein, formaldehyde, acetaldehyde) [15]
Sulfur dioxide [16, 17]
Hydrogen chloride [18]
Hydrogen fluoride [19–21]
Hydrogen bromide [22]
Dimethylamine hydrazine [23]
Zinc chloride [24, 25]
Poorly water-soluble toxic agents (type II exposure)
Nickel [26]
Nitrogen dioxide [27, 28]
Phosgene [29, 30]
Phosphine [31]
Ozone [32, 33]
Non-pulmonary exposure to toxins associated with ARDS
Amiodarone [34, 35]
Aluminum phosphide [36, 37]
Amitriptyline [38]
Ampicillin [39]
Aprotinin [40]
Arsenic [41, 42]
Aspirin [43, 44]
Bleomycin [45]
Carbofuran [46]
Chemotherapeutics [47]
Cocaine [48]
Cyclosporine [49]
Desferrioxamine [50]
Detergents [51]
Dextran [52, 53]
1,3-dichloropropene [54]
Diphenhydramine [55]
Elinogrel [56]
Ethchlorvynol [57]
Ethylene glycol (ingestion) [58, 59]
Fluorocarbon resin [60]
Gemcitabine [61, 62]

(continued)

Table 1 (continued)

Heroin [63, 64]
Ibuprofen [65, 66]
Hydrocarbon [67–73]
Hydrofluoric acid [74]
Lidocaine [75–78]
Lithium [79, 80]
Methadone [63, 64, 81, 82]
Methotrexate [83–85]
3,4-methylenedioxy-methamphetamine (MDMA) [86]
Mercury vapor [37, 87]
Nickel [88]
Nitrofurantoin [89–91]
Nitrogen dioxide [92]
Opioids [63, 64, 93, 94]
Organophosphates [95, 96]
Paraquat [97–101]
Phenol-formaldehyde resin [15]
Phenothiazines [102, 103]
Propylthiouracil [104–106]
Phosgene (inhalation) [29, 30, 107]
Protamine [108, 109]
Quinine and chloroquine [110, 111]
Radiocontrast material (injectable) [112]
Rapeseed oil (denaturated) [113]
Selenious acid [114]
Sodium oleate [115]
Streptokinase [116, 117]
Sulfuric acid fume [118]
Ticagrelor [56, 119]
Transretinoic acid [120]
Tricyclic antidepressants [38, 121, 122]
Welding on metals with galvanized coating or containing zinc chloride or nickel [123, 124]
Zotepine [125]

become evident. Agents that cause a delayed response dissolve poorly in water and therefore penetrate deeper into the lung. Consequently, the process causing symptoms is situated lower in the respiratory tract, which is in the alveoli and the terminal bronchioli.

Type III Inhalation Exposure

In a third type of response to inhalator toxicants, substances are absorbed through the lung but exert

their toxic effect elsewhere in the body. Usually such a toxicant only gives minor irritation in the lung itself. Typical examples of such substances are carbon monoxide or organic solvents, like toluene and xylene [9]. This type of inhalation exposure infrequently gives ARDS. If pulmonary symptoms occur, a type I or type II inhalation injury should be considered. Alternatively, non-pulmonary absorption of lung-damaging toxicants might play a role.

Non-pulmonary Absorption of Lung-Damaging Toxicants

Another important route of pulmonary injury represents lung-damaging toxicants that are absorbed elsewhere in the human body, but, through the circulation, exert their toxic effect in the lungs (indirect injury). This route of exposure is as important as type I and type II exposures but is more difficult to diagnose. A typical example is paraquat intoxication. Paraquat is a synthetic herbicide and when ingested can cause serious damage to various organs, including the lungs. Types I and especially II pneumocytes appear to selectively accumulate paraquat by actively taking up paraquat against the concentration gradient. This results in an additional distribution compartment (the so-called third “toxic effect” compartment) from which paraquat is only slowly eliminated. Biotransformation of the paraquat in these cells results in free-radical production with resulting lipid peroxidation and cell injury (LoE II-3) [126]. While acute pulmonary edema and early lung damage may occur within a few hours of severe acute exposures to paraquat, the delayed toxic damage of pulmonary fibrosis, the usual cause of death, most commonly occurs 7–14 days after the ingestion.

Pathophysiology of ARDS

The normal alveolar epithelium is composed of two types of cells. Flat type I cells make up 90% of the alveolar surface area and are easily injured [127]. Cuboidal type II cells make up the

remaining 10% of the alveolar surface area and are more resistant to injury; their functions include surfactant production, ion transport, and proliferation and differentiation to type I cells after injury. The loss of epithelial integrity in ARDS has a number of consequences. First, under normal conditions, the epithelial barrier is much less permeable than the endothelial barrier [128]. Thus, epithelial injury can contribute to alveolar flooding. Second, the loss of epithelial integrity and injury to type II cells disrupt normal epithelial fluid transport, impairing the removal of edema fluid from the alveolar space [129]. Third, injury to type II cells reduces the production and turnover of surfactant, contributing to the characteristic surfactant abnormalities [127]. Finally, if injury to the alveolar epithelium is severe, disorganized or insufficient epithelial repair may lead to fibrosis (LoE II-3) [130].

The innate immune system plays an important role in the pathophysiology of ARDS. Multiple immunologic processes involving neutrophils, macrophages, and dendritic cells are involved in mediating tissue injury. Toxicological insults affect bronchial epithelium, alveolar macrophages, and vascular endothelium, causing accumulation of protein-rich edema fluid into the alveoli and, consequently, hypoxemia due to impaired gas exchange [127, 131, 132]. Alveolar macrophages play a pivotal role in orchestrating inflammation (LoE II-2) [131, 132]. Once alveolar macrophages are stimulated, they recruit neutrophils and circulating macrophages to the pulmonary sites of injury. These recruited cells secrete a diverse array of bioactive mediators, including proteases, reactive oxygen species, eicosanoids, phospholipids, and cytokines, which subsequently stimulate further inflammatory responses. One of the most notable effects of these mediators is the damage done to adjacent cells, specifically alveolar type 2 epithelial cells [1]. Type 2 alveolar cells serve vital functions by synthesizing and secreting pulmonary surfactant, which is an indispensable material that lines the inner lung surface to lower alveolar surface tension. Type 2 alveolar cells also actively transport electrolytes to control lung fluid. Damage to these cells results in histological changes typical of an

acute exudative phase that results in significant impairment of lung mechanics and gas exchange [127].

Importantly, ARDS is not limited to the lungs, rather it's a systemic inflammatory disease with bidirectional involvement between the lungs and other organ systems [133]. Inflammatory cytokines, such as IL-1 β , TNF- α , IL-6, and IL-8, are elevated both in bronchoalveolar lavage fluid and in the systemic circulation (LoE II-2) [134].

Pattern recognition receptors (PRRs) are essential to the innate immunity, detecting components of foreign pathogens (referred to as pathogen-associated molecular patterns, PAMPs). However, some of these receptors are also able to detect damage-associated molecular patterns (DAMPs) after toxic injury. Toll-like receptors (TLRs) are PRR proteins which appear to be highly conserved molecules throughout vertebrates [135]. Currently, ten functional TLRs have been identified in humans [136]. They recognize PAMPs and DAMPs and trigger a subsequent pro-inflammatory signaling. Development of ARDS appears to be related to TLR signaling pathways. For example, hyaluronan, an extracellular matrix glycosaminoglycan produced after tissue injury, functions as a DAMP for TLR [137]. TLR4 was described as playing a pivotal role in the induction of ARDS in various murine models, TLR2 is implicated in hemorrhage-induced ARDS (LoE III) [138, 139].

In addition to the transmembrane TLRs, nucleotide-binding oligomerization domain-like receptors (NLRs) are cytosolic PRRs that respond to the various PAMPs and DAMPs and trigger pro-inflammatory responses. NLRs are responsible for the sterile inflammation in ARDS. One of them, NLRP (NLR family, pyrin domain containing) is an important component of the inflammasome, a large multiprotein complex. This complex is activated by pore-forming toxins or hypoxic cellular injury and is associated with poorer outcome in patients with ARDS (LoE II-2) [140, 141].

Other molecules, which can be freed into the surrounding tissues or in the circulation after toxic injury, might act as DAMPs as well. For example, mitochondrial DNA and ubiquitin are associated

with ARDS in experimental studies (LoE III) [142–144]. Ubiquitin is a small regulatory molecule found universally in most tissues in eukaryotic organisms. Ubiquitination is a posttranslational modification process whereby ubiquitin is attached to a substrate protein, usually serving as the signal for its degradation via the proteasome or lysosome [145, 146].

The pro-inflammatory signaling of pulmonary macrophages results in influx of neutrophils. Several chemokines, including interleukin 1 β (IL-1 β), IL-6, IL-8, and tumor necrosis factor (TNF), play a central role in regulating neutrophil recruitment and consequent tissue damage, as well as altered alveolar–capillary permeability in both human and animal studies (LoE II-2) [147].

Indeed, histological studies of lung specimens obtained early in the course of ARDS have shown a marked accumulation of neutrophils [127]. Neutrophils predominate in the pulmonary edema fluid and bronchoalveolar lavage fluid obtained from affected patients (LoE II-2) [148]. However, ARDS might develop in patients that are devoid of neutrophils (e.g., profound neutropenia) indicating that neutrophils are important but not critical to the development of ARDS [149].

Macrophages and neutrophils cause (collateral) damage to the pulmonary epithelium (clinically and pathologically presenting as diffuse alveolar damage), which results in filling of the alveoli with protein-rich fluids, cellular debris, and hyaline membranes. Additionally, the alveolar–capillary distance is increased by the formation of collagen [127]. The clinical picture is that of a patient in acute respiratory distress with hypoxia, cyanosis, tachypnea, and radiological manifestations. Arterial hypoxemia that is refractory to treatment with supplemental oxygen is a characteristic feature. Radiographically, the findings are indistinguishable from those of cardiogenic pulmonary edema.

Clinical Definition(s) of ARDS

Clearly, ARDS is not a disease with a well-defined pathophysiology. It should be considered as a set of effects (hence the term “syndrome”) of

Table 2 Different acute respiratory distress syndrome (ARDS) definitions throughout the years. AECC means the American-European Consensus Conference. PaO₂ denotes the partial arterial pressure of oxygen. FiO₂ means the fraction of inspired oxygen. ALI is acute lung

injury. ARDS means acute respiratory distress syndrome. PAOP means pulmonary artery occlusion pressure (also called wedge pressure) which is measured by a pulmonary artery catheter

ARDS definition (1967)					
1. Severe tachypnea, severe dyspnea					
2. Cyanosis that is refractory to supplemental oxygen					
3. Loss of lung compliance					
4. Diffuse alveolar infiltrates of chest radiograph					
Murray score (1988)					
Points	0	1	2	3	4
PaO₂ with F_iO₂ of 100% oxygen (mmHg)	>300	225–299	175–124	100–174	<100
Chest radiograph	Normal	One point for each quadrant involved			
PEEP (cmH₂O)	≤5	6–8	9–11	12–15	≥15
Compliance (ml/cmH₂O)	≥80	60–79	40–59	20–39	≤19
Severe lung injury if average ≥2.5 points					
The AECC definition (1992)					
Oxygenation abnormality					
	ALI	PaO ₂ /F _i O ₂ < 300			
	ARDS	PaO ₂ /F _i O ₂ < 200			
Chest radiograph		Bilateral infiltrates and pulmonary edema			
PAOP < 18 mmHg (or no clinical evidence of left atrial hypertrophy)					
The Berlin definition (2012)					
Timing	Acute onset within 1 week of a known clinical insult or new/worsening respiratory symptoms				
Chest radiograph	Bilateral opacities, not explained by effusions, lobular collapse, nodules				
Origin of edema	Respiratory failure not explained by cardiac failure or fluid overload				
	Need of objective assessment (e.g., echocardiography) to exclude hydrostatic edema if no risk factor is present				
Severity					
Hypoxemia	Mild	Moderate		Severe	
	PaOPaO ₂ /F _i O ₂ 200–300 mmHg with PEEP ≥ 5 cmH ₂ O	PaO ₂ /F _i O ₂ 100–200 mmHg with PEEP ≥ 5 cmH ₂ O		PaO ₂ /F _i O ₂ < 100 mmHg with PEEP ≥ 5 cmH ₂ O	

incompletely understood pathophysiology. As a consequence, the clinical definition of ARDS has changed through the ages.

The first description of ARDS was published in 1967 by Ashbaugh and colleagues and combined clinical and laboratory results (LoE III) [150]. The original clinical pattern included severe tachypnea, cyanosis that was refractory to oxygen supplementation, the loss of lung compliance, and diffuse alveolar infiltrates on a chest radiograph. Despite the fact that this definition of ARDS was

nonspecific and was dichotomous, it was used for many decades (see Table 2).

In 1988, Murray and colleagues elaborated on this model and added a grading system to the definition [151]. This so-called Murray score introduced the ratio of partial pressure of arterial oxygen (PaO₂) and inspired fraction of oxygen (F_iO₂) as a measure of severity of ARDS (see Table 2). If the patient had an average Murray score exceeding 2.5 points, the ARDS was considered severe (LoE III).

Fig. 2 Slowly declining 28-day mortality in the control arms of the randomized controlled trials on ARDS. The size of the dots represents the amount of patients in the control arm only [160–169]

In 1992, the American-European Consensus Conference came up with a distinction between acute lung injury (ALI) and ARDS depending on the severity of the $\text{PaO}_2/\text{F}_i\text{O}_2$ ratio (LoE III). An important improvement was the exemption of cardiogenic edema as a cause of respiratory failure. By definition, the patient needed to have a pulmonary artery occlusion pressure (PAOP) of less than 18 mmHg; otherwise, it is considered congestive pulmonary edema. The severity of the ALI/ARDS was correlated with mortality outcome. Mortality of severe ARDS ($\text{PaO}_2/\text{F}_i\text{O}_2$ ratio < 100 mmHg) exceeded 50% in some studies, although the ARDS-associated mortality declined throughout the years (LoE II-1) [152].

However, distinction in severity (ALI vs. ARDS) was dismissed with the introduction of the Berlin criteria 2012. What used to be called ALI is nowadays called “mild ARDS.” The added value of the latest definitions is a distinction between “moderate ARDS” and “severe ARDS” ($\text{PaO}_2/\text{F}_i\text{O}_2$ ratio < 100 with a positive end-expiratory ventilation pressure of at least 5 cmH_2O) (LoE III) [153, 154].

None of the consensus definitions were able to discern different types of ARDS, nor was it possible to separate distinct pathophysiological

pathways. At present, the lack of knowledge of the underlying pathophysiological processes makes it impossible for clinicians to separate different forms of ARDS. However, it is unlikely that ARDS resulting from an infectious origin is completely the same as ARDS from a toxicant. Unfortunately, at present we still have to assume that they are all the same and the pathophysiological pathway in infection (PAMPs) is the same as in toxic injury (DAMPs).

Mortality of ARDS

Differences in definitions and study populations throughout the years make it virtually impossible to compare mortality rates of ARDS patients. In the 1980s, the mortality of ARDS was 60–80% and this slowly declined to a mortality of 30–40% in the 2000s (see Fig. 2) (LoE I) [155, 156]. Patients with more severe respiratory failure had higher associated mortality rates (see Fig. 3). Obviously, mortality might be associated with factors other than ARDS itself. Some studies suggest that the mortality is related to the development of multi-organ failure or sepsis. In patients with ARDS, the primary cause of death was sepsis

Fig. 3 Mortality of ARDS based upon severity ($\text{PaO}_2/\text{FiO}_2$). See text for more details

and multi-organ failure (49%), refractory hypoxia (16%), cardiac failure (15%), and neurologic failure (10%) (LoE III) [157]. Patients with ARDS as a result of sepsis had a higher mortality than patients with other causes of ARDS. However, most of these ARDS mortality rates are derived from studies in which most patients have sepsis-associated ARDS rather than toxin-induced ARDS. Information on toxic ARDS is limited to case reports and observational studies and is often intertwined with patients with toxic circulatory shock. Mortality rates are therefore difficult to extrapolate, but are reported to be as high as 48% (LoE III) [2, 158, 159].

Treatment of ARDS

The ultimate goal of treatment in ARDS patients is to provide the other organs sufficient oxygen to prevent secondary organ damage, or even organ failure, and to prevent unnecessary damage to the already damaged lungs.

Although this seems obvious, there are no absolute cutoff points that define severity of ARDS. Certain patients are moderately ill with $\text{PaO}_2/\text{FiO}_2$ ratios <300 , while others at this same ratio are severely respiratory compromised and need immediate mechanical ventilation. The consensus definitions have aided in the identification of ARDS, but the treatment remains individualized. However, the common goal of ARDS treatment is “do no further harm,” and this has been merged into the “lung-protective ventilation”

strategy, which consists of low tidal volumes, high positive end-expiratory pressure (PEEP), recruitment maneuvers, and prone positioning of the patient (see next paragraphs for more details).

Lung-Protective Ventilation

Gattinoni and coworkers were among the first to notice three distinct regions in ARDS-affected lungs: normal lung tissue, a region densely consolidated, and a region that collapses during expiration and is recruitable during inspiration (LoE II-2) [170]. When these heterogeneous lungs are ventilated (even at low tidal volumes) in the absence of PEEP, they present a repetitive opening and closing of airways and lung units [171]. This type of injury is called “atelectrauma” [171]. However, if these heterogeneous lungs are ventilated with higher tidal volumes, over distension of alveoli may occur, leading to “barotrauma,” which causes complications such as pneumothorax (LoE II-2) [172]. A third form of ventilator-induced lung injury is called “biotrauma,” which is a systemic inflammatory response syndrome as a consequence of a release of lung cytokines (e.g., $\text{TNF-}\alpha$, IL-6, IL-8) (LoE II-2) [173]. Clearly, mechanical ventilation poses potential harm to patients, and therefore mechanical ventilation should be as “protective” as possible.

Amato and colleagues were the first to show that smaller tidal volumes while being ventilated were associated with improved outcome (LoE I)

[160]. Up to this study, most patients were usually ventilated with higher tidal volumes (~ 12 ml/kg of ideal body weight or more). This study showed that mortality from ARDS could be reduced from 71% to 38% by applying a lower tidal volume approach (~ 6 ml/kg ideal body weight). However, the mortality in the control arm of this study was disproportionally high in comparison to the background mortality of ARDS (30–40%) at that time period (see Table 2). Hereafter, several randomized controlled trials have attempted to show that lower tidal volumes that prevent mortality have had varying results [160–164, 174]. A meta-analysis summarizing the clinical effects of ventilatory components on the outcome of patients with ARDS [175] found that mechanical ventilation strategies that use lower end-inspiratory (plateau) airway pressures, lower tidal volumes, and higher PEEP can improve survival, but the relative importance of each component has not been established (LoE I). In this study, all individual patients from nine previous randomized clinical trials were reassessed. They found that small tidal volumes per se were not associated with better outcome, but lower driving pressures were (pressure needed to achieve a tidal volume) [175, 176]. When patients were matched according to PEEP level, higher peak pressures were associated with increased mortality. However, if patients were matched for driving pressure, higher levels of PEEP were not associated with decreased mortality. Further, if they matched patients with the same level of plateau airway pressures, higher levels of PEEP (and, inversely, lower driving pressures) were associated with lower mortality (LoE II-1). These data demonstrate that, despite several randomized clinical trials in ARDS, we do not yet know which ventilation strategy is optimal for the individual patient.

The general concept arising from these reanalyses is that not the highest PEEP, but the lowest driving pressure, should be the ventilation target. In summary, the driving pressures should be kept below 15 cm H₂O and the plateau ventilation pressures below a 30 cm H₂O (LoE III).

Oxygen and Fractional Inspired Oxygen

In the earlier ARDS trials, the fractional inspired oxygen (F_iO_2) was arbitrarily coupled to the amount of PEEP. The higher the PEEP, the higher the F_iO_2 . However, several observational studies have shown that higher levels of PaO_2 were associated with higher mortality (LoE II-2) [177]. Many of these studies may not have appropriately corrected for confounders, and thus controversies remain regarding these issues. Indeed, other studies were unable to confirm these findings [178, 179]. Still, the pragmatic advice is to lower the FiO_2 as long as the arterial oxygen saturation (S_aO_2) remains 88–92% (LoE III).

Rationale for Lung-Protective Ventilation

In patients with toxic pulmonary damage, the levels of pro-inflammatory cytokines, such as IL-1 β , TNF- α , IL-6, and IL-8, are elevated (LoE II-2) [180]. However, mechanical ventilation itself may cause pro-inflammatory signals [173], especially if the ventilation cannot be kept protective. ARDS is distributed unevenly throughout the lungs, which means that certain areas of the lung will not be ventilated while other parts might get hyperinflated. Even protective ventilation with tidal volumes that do not exceed 6 ml/kg of ideal body weight might result in hyperinflation of the more compliant lung areas. Patients that did have such hyperinflated areas comprising greater than 60% of the total lung had higher levels of pro-inflammatory cytokines in their bronchoalveolar lavage fluid, such as IL-6, IL-1 β , IL-1, IL-8, and TNF- α [181]. This is suggestive that less protective ventilation might lead to “ventilator-induced lung injury.” Repeated overstretching of alveoli, continuous recruitment and derecruitment, and shear stress can lead to cytokine production and subsequent multi-organ failure (LoE II-2) [165]. Obviously, lower tidal volumes are preferred but might be challenging due to insufficient ventilation, leading to hypoxia and hypercapnia. This

might be overcome by extracorporeal removal of carbon dioxide and/or extracorporeal membrane oxygenation, a concept that has been coined “lung rest” (see further section on “[Extracorporeal Membrane Oxygenation \(ECMO\)](#)”).

Prone Positioning of the Patient

In a normal healthy lung, blood flow is distributed evenly. However, when lungs are inflamed and become heavier, some parts of the lung get less blood flow, especially the gravitationally compressed dorsal parts. Putting a patient in a prone position reverses this, and the volumetrically larger dorsal parts get better perfused and ventilated [182]. Obviously, this does not apply to all patients as ARDS is not homogeneously distributed and varies considerably between patients. However, in a recent randomized controlled trial in patients with severe ARDS (defined as a $\text{PaO}_2/\text{FiO}_2$ ratio < 150), prone positioning led to significantly lower mortality after 90 days (hazard ratio for mortality after correction for severity of illness was 0.48 with confidence intervals (0.32–0.72, $p < 0.001$)) (LoE I) [169]. This was confirmed in a meta-analysis of 9 studies evaluating the effect of prone positioning (LoE I) [183]. Once the lungs are recruited in prone position, the lungs should remain recruited by applying sufficient PEEP. However, the appropriate amount of PEEP is still being debated. Obviously, enough PEEP should be applied to prevent derecruitment, but, as explained previously, higher levels of PEEP are not always beneficial. A pragmatic approach would be to choose the level of PEEP at which the highest total respiratory system compliance occurs by descending PEEP titration (LoE III) [175]. This corresponds to the lowest driving pressure for appropriately sized ventilation tidal volumes. However, overdistention and regional collapse may still occur, and repeated CT scans and/or potentially electrical impedance tomography may be needed to follow up proper ventilation dynamics (LoE II-3) [184–188].

Corticosteroids

Corticosteroids have been used and advocated for in numerous toxic inhalational injuries. There are many, at least theoretical, reasons why corticosteroid treatment might be beneficial [189]. Corticosteroids exert strong anti-inflammatory properties by means of switching off pro-inflammatory genes and transcription factors (LoE II-2) [190, 191]. These anti-inflammatory effects could be beneficial in patients who are suffering from toxic inhalational ARDS. This hypothesis has been tested in various animal and human volunteer studies [1]. Unfortunately, interpretation of many of these studies is seriously hampered by the difficulty in translating animal data to the humans. In addition, positive effects of corticosteroids were mostly seen on intermediate endpoints, such as respiratory resistance in the acute phase of intoxication. Longer-term outcomes were most often not assessed. Yet, corticosteroids did not seem to have any beneficial effect at the alveolar level and might even have had a detrimental effect on alveolar repair mechanisms (LoE II-3) [192–194]. This might be explained by the inhibitory effect on the division of corticosteroids on type II alveolar cells. These cells are essential for the reepithelialization of the alveolus [195, 196]. Understandably, there are no human intervention trials to ascertain the efficacy of corticosteroid treatment following deliberate severe exposure to lung-damaging agents.

Human data on acute, high level exposure to lung-damaging agents are limited to anecdotal reports describing accidental exposure. Most of this circumstantial evidence from “natural experiments” lacks important information, such as duration of exposure, ambient gas concentrations, environmental conditions, presence of other toxins, and breathing pattern. These case reports are therefore limited in their ability to establish a cause–effect relationship for the treatments involved [1]. A few randomized studies exposed subjects to a low inhalational dose of a lung-damaging agent. These studies showed that even pretreatment with an inhalational corticosteroid did not prevent a decline in pulmonary function (LoE I).

Again, long-term outcome was not assessed [197, 198]. A systematic review on the use of corticosteroids for lung-damaging agents concluded that, at present, there is no convincing evidence that corticosteroids have a beneficial influence on the outcome of animals or humans who are exposed to inhalational toxins (LoE III). On the other hand, adverse side effects of corticosteroid treatment are well established (e.g., prolonged neuromuscular weakness, deregulation of glucose metabolism, superinfection, and sepsis) [1].

Circumstantial evidence might be derived from corticosteroid treatment in patients with other nontoxic causes of ARDS. Unfortunately, meta-analyses of corticosteroid treatment in such patients have yielded contradictory results. One meta-analysis [199] found a significantly reduced mortality, while three other studies found a nonstatistically significantly reduced mortality for corticosteroids (LoE I) [199–202]. The meta-analyses [199] showed that corticosteroids decreased the length of stay in the intensive care unit (ICU) and decreased the length of mechanical ventilation. Yet, corticosteroids that were started in the late fibroproliferative phase (≥ 14 days after the onset of ARDS) were associated with a worse outcome (LoE I). The optimal timing of corticosteroids, if existing at all, remains undetermined. Therefore, at present, the use of corticosteroids in inhalational toxic ARDS is not advocated (LoE III) [1].

Sedation and Paralysis to Improve Ventilation

Patients with ARDS have extreme “air hunger” and high minute ventilation. It has been suggested that neuromuscular blockade will benefit these patients. This will eliminate asynchrony with the ventilator and might increase chest wall compliance leading to lower driving pressure for the protective, small tidal volumes that need to be applied. One randomized clinical trial showed a better outcome if neuromuscular blockade was used in the first 48 h of mechanical ventilation (LoE I) [203, 204]. However, prolonged application of sedation and neuromuscular blockade is

opposing the currently held belief that sedation should be kept at minimal levels. Overuse of sedative–analgesic medication has been associated with prolonged mechanical ventilation and might even increase mortality (LoE I) [205, 206]. Obviously, this is evidence that has been derived from critically ill patients that are mechanically ventilated and whether this holds true for the subgroup of patients with toxic ARDS, although common sense dictates so, needs to be determined.

Antibiotic Prophylaxis in Toxic ARDS

Another commonly applied treatment for which there is hardly any empirical support is the prophylactic treatment of patients with inhalational injury with antibiotics. A study on medications given to patients with ARDS reported that 19% of ARDS patients had a noninfectious etiology, yet all received antibiotics [207]. Another small study showed that 18 (30%) of 30 patients with severe ARDS developed nosocomial pneumonia [208]. These studies illustrate that it is very difficult to discern infection from an already inflamed lung parenchyma and many physicians treat such patients prophylactically or empirically. An invasive approach to diagnosis ventilator-associated pneumonia in patients with ARDS by means of bronchoalveolar lavage with quantitative cultures of pathogens reduces the length of antibiotic treatment, the total amount of antibiotics that are being prescribed and might even reduce mortality (from ventilator-associated pneumonia) (LoE I) [209].

Extracorporeal Membrane Oxygenation (ECMO)

Hypoxia resulting from toxin-induced ARDS needs to be reversed immediately in order to prevent multi-organ failure. Since the 1970s, extracorporeal membrane oxygenation (ECMO) has been used to treat severe ARDS [210]. In the beginning, ECMO was a cumbersome treatment

Fig. 4 VV-ECMO and VA-ECMO: In veno-venous extracorporeal membrane oxygenation (VV-ECMO), blood is withdrawn from a large vein (e.g., femoral vein or inferior vena cava), led through a pump and oxygenator. Oxygenated blood is returned to a large vein in proximity to the heart (e.g., *right* jugular vein or in the inferior vena cava). In venoarterial ECMO (VA-ACMO or ECLS),

blood is drawn from a large vessel and after oxygenation returned to the descending aortic arc. VV-ECMO is used for oxygenation of blood whenever circulation is sufficient. VA-ECMO is used to support a failing circulation (This figure was copied from De Lange et al. Ref. [2], copyrights © (2013), Informa Healthcare. Reproduced with permission of Informa Healthcare)

with many adverse effects. Therefore, it was abandoned in most hospitals treating adult patients. In critically ill children and neonates, however, ECMO remained a salvage treatment for severe respiratory failure. However, in 2009, the influenza A/H1N1 pandemic caused severe and refractory ARDS in many patients, requiring ECMO as a salvage therapy. The mortality rate for ECMO-treated patients was surprisingly low (~25%), despite them being severely hypoxic patients (LoE II-2) [211]. At that time, ECMO was increasingly applied as an assist device for cardiothoracic patients needing oxygenation as well as circulatory support. Moreover, the equipment was more biocompatible and better constructed than prior devices [212, 213]. These encouraging results ignited new interest in ECMO for severe ARDS, and many hospitals around the world have now adopted ECMO as a salvage therapy for ARDS.

ECMO Techniques

Several high-quality reviews have been published that eloquently describe how ECMO works (see Fig. 4) [2, 214–216]. Basically, there are two ECMO modalities. In veno-venous ECMO (VV-ECMO), hypoxic blood is withdrawn from a large-bore peripheral vein, often the femoral vein. This vein can be accessed percutaneously, which makes it easily accessible in emergency settings. The blood is then oxygenated and pumped back to the right atrium through a percutaneously placed catheter in the upper or lower vena cava. This technique preserves pulmonary blood flow, pulsatile systemic flow, and the oxygenated blood in the left ventricle and aortic root [214]. An additional advantage of this technique is that the lungs function as a natural filter for emboli that might be caused by the artificial

ECMO materials. Acute right ventricle failure due to ARDS, in itself, is not a contraindication for VV-ECMO. Oxygenation of the pulmonary artery blood will decrease the hypoxia-induced vasoconstriction and ameliorate pulmonary resistance (LoE II-2) [214]. Additionally, mechanical ventilation pressures can be reduced, because the gas exchange can occur by way of VV-ECMO. By lowering mechanical ventilation pressures, intrathoracic pressures will decrease. This will reduce pulmonary vascular resistance and thus the workload of the right ventricle.

VV-ECMO may not be adequate when ARDS is accompanied by severe circulatory shock. In that case, venoarterial ECMO (VA-ECMO; Fig. 4) is more appropriate. In VA-ECMO (also called “extracorporeal life support,” ECLS), hypoxic blood is drawn from the vicinity of the right ventricle through a large-bore cannula. This cannula will usually be placed percutaneously through the right jugular vein. However, the right atrium can also be accessed through the femoral vein. The latter is especially useful in emergency settings, for example, when cardiopulmonary resuscitation is performed and chest compressions prevent proper and hygienic placement of the catheter through the right jugular vein. The blood is then pumped through the oxygenator and returned to the patient via another catheter into the aorta. If the latter cannula is placed percutaneously, then the blood is pumped back into the descending aorta.

Although VA-ECMO is useful in emergency settings, it harbors some dangers. First, the large-bore catheter in the femoral artery might compromise perfusion of the lower extremity and result in ischemia in up to 21% of patients (LoE II-2) [217]. Second, because of considerable reduced blood flow through the pulmonary circulation, thrombus formation is possible. Third, the blood supply to the systemic circulation is dual; hypoxic blood is pumped through the lungs and mixed with oxygenated blood from the ECMO circuit in the descending aorta. As a consequence, the more cephalad organs, such as the brain and the heart, receive less oxygenated blood compared to the caudal organs (LoE II-2) [218]. This can easily be checked by measuring O_2 saturation at the earlobe or nostril. If decreased oxygenation

occurs, and circulatory shock is not reversed within an acceptable time, a more central cannulation needs to be performed. In this case, a cardiothoracic surgeon should place the afferent cannula in the ascending aortic arc or in the apex of the left ventricle. However, doing so requires a sternotomy. This emphasizes that VA-ECMO should be reserved only for patients with accompanying refractory circulatory shock and is best avoided if only ARDS is present.

Despite the fact that, at present, more and more hospitals are using ECMO as salvage therapy, evidence for its efficacy is lacking. A recently published trial conventional ventilatory support versus extracorporeal membrane oxygenation for severe adult respiratory (CESAR) failure compared ECMO with conventional mechanical ventilation in patients with ARDS [219]. This trial included adult patients up to 65 years of age with a Murray score of 3.0 and higher, or uncompensated, hypercapnia with a pH less than 7.20, despite “optimum conventional treatment.” However, patients were excluded if they had received high ventilation pressures (peak inspiratory pressures 30 cmH₂O or F_iO_2 of 80% for more than 7 days). Eligible patients were then randomized to continuing of conventional mechanical ventilation ($n = 90$) or referral to an ECMO center ($n = 90$). Unfortunately, some patients died before transfer or during transit and 16 patients did not receive ECMO. Eventually 68 patients were treated with VV-ECMO. Six months after randomization, the composite endpoint of death or severe disability was seen in 33/90 ECMO patients and 46/90 patients in the conventional group ($p = 0.03$) (LoE I).

However, the results of the CESAR trial have been criticized. Opponents argue that the patients in the conventional arm trial did not get standardized treatment, and the “center experience” in the ECMO arm led to an improved outcome in patients randomized to the ECMO arm. However, despite methodological issues, VV-ECMO emerges from this trial as a salvage therapy with lifesaving abilities. At present, trials, like the French EOLIA trial, are currently underway, and early VV-ECMO in ARDS is being compared with optimal protective mechanical ventilation in the control group.

The degree of physiological decline, or expected decline, may be more important than the absolute extent of ventilatory support, and it is important that ECMO referrals are made in sufficient time to allow patient assessment, cannulation, and, in some instances, transfer to another institution (LoE III) [220]. Generally, if transport to another institution is required, a specialized ECMO retrieval team should travel to the referring institution and cannulate the patient on location before transportation. After the cannulation, the patient can then be transported to a hospital with ECMO experience. Outcome can be improved by keeping to these principles (LoE II-3) [214, 219, 221].

Cost Effectiveness

The goal of ECMO is to keep patients alive who would otherwise die despite maximum conventional treatment. Preferentially, ECMO is used as a “bridge to recovery.” Sometimes, the damage to organs is irreversible and then ECMO can be used as a “bridge to transplant” [2, 98, 101]. However, ECMO is a complex, resource-consuming expensive therapy. Although research has been scarce, there is ample evidence that ECMO is able to save many life years and the quality of life adjusted life years saved compare favorably to many other currently available treatments, such as hemodialysis, implantation of cardiac assist devices, or implantable cardioverter defibrillators (LoE II-3) [222–227].

The use of ECMO in poisoned patients is described in greater detail in the chapter on that topic.

Long-Term Outcome

The ultimate goal of critical care treatment is not merely “hospital survival.” The toxicological literature and especially case reports often focus on hospital discharge as the primary outcome measure. However, for several reasons, subsequent mortality may still be higher than expected for many months after discharge. First, patients may

have an increased mortality risk due to critical illness-related disorders, such as weakness, immunological insufficiency, or other comorbidities. Second, patients may still be moribundly ill at hospital discharge, i.e., if they are discharged from one hospital to another or to a palliative care facility. Third, the critical illness and ICU admission may accelerate the underlying diseases (LoE II-2) [228, 229]. If the patient is discharged alive but dies within weeks after discharge, this can hardly be considered “a good outcome,” and, in retrospect, the entire treatment could be considered futile [229, 230]. In a large Dutch observational cohort of intoxicated patients ($n = 7,331$), the average mortality rate 2 years after ICU discharge was 9.3%. This was substantially higher than could be expected based on their age and gender (LoE II-2) [231]. The reasons for this higher mortality are currently unknown [232]. Hypothetically, organ failure caused by the lung-damaging agent or multi-organ failure due to, or in spite of, mechanical ventilation might lead to premature aging of organs. This is especially true for the more seriously ill intoxicated patients with ARDS. Unfortunately, research in this area is lacking. Extrapolating research from ARDS patients due to infections shows that the mortality at 1 year is substantially higher than the in-hospital mortality (41% vs. 21%, respectively, $p < 0.0001$) (LoE II-2) [233, 234].

Another important outcome for those who survive beyond the initial first months of ICU discharge is quality of life. Patients who survive severe ARDS or an inhalational intoxication have a lower than average quality of life and more post-traumatic stress disorder (LoE II-2) [235–238]. However, which components or variables attribute to this lower quality of life is unclear and requires further research.

Conclusions and Recommendations to Overcome Areas of Uncertainty

ARDS is a clinical syndrome that can arise from many insults: infectious, inflammatory, and toxic. The true mechanism of toxin-induced ARDS is

unknown, but evidence extrapolated from other sources of ARDS can be extrapolated to toxic ARDS. Such knowledge from, predominantly, infectious ARDS is currently the best evidence to guide toxic ARDS. In general, patients should be treated in order to prevent secondary (multiple) organ damage. If patients need mechanical ventilation, further damage through ventilation itself should be avoided. The best strategy currently available is “protective ventilation,” which consists of low tidal volumes (~6 ml/kg ideal body weight or even less), PEEP titration to such a level that the driving pressure for tidal volumes is as low as possible (or, vice versa, total compliance of the lung is largest), decreasing driving pressures to ≤ 15 cm H₂O, and oxygen supplementation kept as low as possible while maintaining appropriate arterial oxygen saturations (88–92%). If, with the abovementioned strategy, plateau pressures cannot be kept below 30 cm H₂O, salvage therapies, such as ECMO, should be considered. Treatments with corticosteroids or antibiotics solely for toxic ARDS are not based upon sufficient evidence and should be discouraged. Long-term outcome of victims of toxic ARDS (both long-term survival and quality of life) is yet to be incorporated in future research. Clinical toxicology is in desperate need for more, preferably randomized, trials evaluating our current treatment options. Additionally, (inter)national registries for patients with intoxications, such as the Toxicology Investigators Consortium, are needed to improve the evidence we currently have and on which we base all our treatments.

Acknowledgments Parts of this chapter are based upon chapters written by Dorsett D. Smith and Jeffrey L. Burgess in previous editions of this book.

The sudden failure of a previously healthy and functioning liver is a dramatic and devastating event. Acute liver failure is the common final pathway of a multitude of conditions and insults, all of which result in massive hepatic necrosis or loss of normal hepatic function. The ensuing multiorgan system failure frequently has a fatal outcome, with mortality rates in most series ranging from approximately 55% to 95% [1]. Acute liver failure (ALF, previously often referred to as fulminant hepatic failure (FHF)) knows no age boundaries, with many cases occurring in those younger than 30 years. Short of excellent intensive care unit (ICU) support and liver transplantation in selected cases, few viable treatment options are available. Over the past few decades, however, survival has been improved by anticipation, recognition, and early treatment of associated complications, as well as the application of prognostic criteria for early identification of patients requiring liver transplantation (along with improvement in the techniques and science of transplantation itself). The etiology of ALF varies from country to country and the incidence change over time. Paracetamol (acetaminophen) has now replaced viral hepatitis as the leading cause of ALF [2]. In a study from London including 310 patients with ALF in the period 1994–2004, 42% of the cases were caused by paracetamol [3], whereas this was only the cause in 2% of 267 patients in Spain from 1992 to 2000 [4]. However, less than 10% of all liver transplants are performed in patients with ALF [5, 6].

The aim of this chapter is to help clinicians recognize the presentation and clinical features of drug- or chemical-induced ALF or liver injury, anticipate and appropriately manage the complications of ALF, and recognize the indications for timely referral for orthotopic liver transplantation (OLT). The pathophysiology, differential diagnosis, appropriate laboratory testing in the evaluation and treatment of ALF, and specific therapies available for certain etiologies of ALF will also be discussed. Current and future trends in liver transplantation will be described.

Definitions

In 1986, Bernuau and colleagues [7] suggested that the term “fulminant hepatic failure” (FHF) should be applied to patients in whom encephalopathy developed within 2 weeks of the onset of jaundice and that subfulminant hepatic failure be applied to those in whom this interval was 2–12 weeks. In 1993, O’Grady and associates [8] proposed the terms hyperacute, acute, and subacute liver failure based on whether the interval between the appearance of encephalopathy and jaundice was 0–7 days, 8–28 days, or 29 days to 12 weeks, respectively. Both Bernuau and O’Grady included cases of preexisting asymptomatic chronic liver conditions. In Japan, patients with fulminant hepatitis are classified into two types according to the onset of encephalopathy (before or after 10 days). Encephalopathy occurring after 8 weeks is defined as late-onset hepatic failure (LOHF) [9].

These classification systems reflect important differences in the clinical course and prognosis observed between patient subgroups, thus facilitating earlier diagnosis and timely referral for OLT. For example, both the hyperacute and acute liver failure groups have a high incidence of cerebral edema. However, whereas patients in the hyperacute group are more likely to survive with medical management, patients in the acute liver failure group tend to die without liver transplantation [8]. The subacute failure group has a lower incidence of cerebral edema and a higher incidence of portal hypertension manifestations, including ascites and renal failure [8]. Mortality in this group remains high. O’Grady and colleagues found that the hyperacute failure group had a 36% survival rate, as opposed to 7% and 14% in the acute and subacute failure cohorts, respectively [8]. Bernuau and coworkers also noted that those with the most rapid onset of encephalopathy had the best chance of survival [7]. Similar observations have been made in Japan [9]. However, it is important to note that although the interval between the onset of encephalopathy and jaundice

Table 1 Definitions of liver failure

Bernuau [7]	Fulminant hepatic failure: encephalopathy within 2 weeks of onset of jaundice
	Fulminant hepatic failure: encephalopathy within 2–12 weeks of onset of jaundice
O’Grady [8]	Hyperacute liver failure: encephalopathy within 7 days of onset of jaundice
	Acute liver failure: encephalopathy within 8–28 days of onset of jaundice
Tandon [12]	Subacute liver failure: encephalopathy within 5–12 weeks of onset of jaundice
Mochida [9]	ALF defined as liver disease ≤ 26 weeks in duration, $\text{INR} \geq 1.5$, and any degree of encephalopathy
	Fulminant hepatic failure: encephalopathy within 8 weeks of onset of jaundice
	Subclass acute: encephalopathy within 10 days of onset of jaundice
	Subclass subacute: encephalopathy within 10 days to 8 weeks of onset of jaundice

was of prognostic significance in O’Grady’s cohort [1], it was not an independent prognostic factor in Bernuau’s cohort [10], thus raising doubts about its universal applicability. Application of the O’Grady classification to 423 prospectively studied patients from a tertiary care referral center in northern India failed to yield any prognostic differences between the groups [11].

Although these classifications may be useful in highlighting differences in clinical course and prognosis among patient subgroups, the contribution of other independent prognostic indicators (etiology of ALF, patient age, prothrombin time, factor V level, renal function, mental status) should not be overlooked. Table 1 provides a summary of the various definitions of liver failure.

Pathogenesis

Measuring about 1500 mL in volume, the liver is the second largest organ in the body and plays a critical role in its homeostasis. At no time is this role more apparent than during an episode of acute injury. Derangements in synthetic function

(hypoalbuminemia, decreased levels of clotting factors), gluconeogenesis (hypoglycemia), drug and toxicant metabolism (sensitivity to narcotics and benzodiazepines, hyperammonemia), excretory function (hyperbilirubinemia), temperature regulation (hypothermia), and central nervous system function (encephalopathy) are the result of liver failure. Some of these parameters are used as prognostic factors and markers of severity of injury.

The exact mechanisms of injury and impairment in hepatocellular function that lead to ALF are poorly understood. Loss of integrity of the hepatocyte plasma membrane secondary to chemical, immunologic, or a wide variety of other insults is thought to represent the final common pathway that leads to cell necrosis and ALF [13, 14]. Damage to the cell membrane permits leakage of enzymes, coenzymes, and electrolytes from the cytosol, followed by an influx of calcium ions, which eventually results in cell death. The importance of calcium is underscored by the finding that normally vulnerable hepatocytes in vitro do not succumb to the cytotoxic effects of membrane-active toxins when calcium ions are not included in the culture medium [15].

New information is emerging on the role of growth factors and the inflammatory cascade in ALF. Transforming growth factor- β_1 (TGF- β_1) has been identified as exerting an inhibitory effect on hepatic regeneration, with its effects being counteracted by hepatocyte growth factor (HGF). ALF patients with viral hepatitis have demonstrated an increase in total TGF- β_1 with a less elevated HGF level, thus suggesting an imbalance in growth factor interplay as a cause of impaired hepatic regeneration [16]. This mechanism has also been suggested by research performed in posttransplant patients [17]. Studies suggest that activation of the cytokine network may represent the common final pathway for the development of ALF [18]. Although multiple inflammatory cascades come into play, interleukin-1, interleukin-6, and tumor necrosis factor- α have been identified as the more important

mediators, along with endotoxin and nitric oxide. In response to the initial hepatic insult, interplay among these mediators sets into motion a vicious self-perpetuating cycle resulting in continued hepatic injury and multiorgan failure. Furthermore, higher levels of circulating interleukin-8 and interferon- γ have been demonstrated in patients with ALF than in healthy volunteers and those with chronic liver disease, thus suggesting a pathogenic role in acute hepatic injury. Although no relationship was found between the levels of these two markers and the clinical course, elevated levels of interleukin-10 were found to be predictive of improved outcome [19].

Etiology and Differential Diagnosis

Careful diagnostic evaluation is important because the etiology can have prognostic implications (e.g., the prognosis is worse with Wilson's disease and idiosyncratic drug reactions, better with viral- and acetaminophen-induced ALF), influence treatment options (e.g., *N*-acetylcysteine [NAC] for ALF induced by acetaminophen [acetyl-*para*-aminophenol or paracetamol]), and indicate the need for genetic testing of family members (e.g., Wilson's disease) [20]. Etiologies of ALF can be divided into toxic and nontoxic. Toxic causes include pharmaceuticals, drugs of abuse, chemicals, and biologic agents. Nontoxic causes include, but are not limited to, infections, ischemia, metabolic derangements, malignancy, autoimmune problems, and primary graft failure after liver transplantation. Because ALF represents the common final pathway of injury, it is difficult to differentiate between the aforementioned causes based solely on clinical presentation and disease progression. A detailed patient history is invaluable, and a multitude of helpful diagnostic testing tools are available to help uncover the etiology of ALF in the majority of cases (Table 2).

Frequency of Causes

Although the frequency varies geographically, the most common causes of ALF remain viral and

drug-induced hepatitis. In the USA, drug-induced liver injury is responsible for almost 50% of ALF [21, 22] most often caused by APAP. In London, UK, APAP poisoning was responsible for 57% of ALF cases seen at King's College Hospital between 1973 and 1991, whereas in France, APAP was identified as the etiology in only 2% of ALF cases between 1972 and 1990 [23, 24]. A multicenter study from the USA of 295 patients in whom ALF was diagnosed between 1994 and 1996 found that the most common etiologies were APAP (20%), viral hepatitis (10% hepatitis B, 7% hepatitis A), cryptogenic (15%), and drug reactions (12%) [25]. Outside of the USA and Europe, drugs are less likely to cause ALF. In a Japanese study [26], the percentage of drug allergy-induced ALF in 432 patients collected in the period 1998–2006 was 2% in contrast to viral infection which was diagnosed as the cause in 16% of the patients (13% with hepatitis B). Even though APAP overdose was found to represent one-sixth of all causes of ALF leading to registration for liver transplantation in Europe, there was a 50-fold difference in the relative risk of ALF leading to registration for liver transplantation between countries with a low incident rate (e.g., Italy with 0.03 ALF per million inhabitants per year) and high incident rate (e.g., Ireland with 7.13 ALF per million inhabitants per year). The reasons for these differences remain unclear, but may be related to national differences in pack size restriction of APAP or antidote treatment regimens [27].

Toxic Causes

Pharmaceuticals

Hepatotoxicity can result from therapeutic or toxic doses of many medications by a multitude of mechanisms. It can be manifested as asymptomatic elevations of liver enzymes, but some cases can progress to ALF. Hepatocyte injury can occur directly from disruption of intracellular function or membrane integrity or indirectly from immune-mediated membrane disruption. Drugs can also cause cholestasis, steatosis, idiosyncratic reactions, fibrosis, veno-occlusive disease,

Table 2 Etiology of acute liver failure

Infections	Toxins/chemicals	Vascular	Metabolic/ others
Viral hepatitis	Cyclopeptide mushrooms	Budd–Chiari syndrome	Wilson’s disease
Hepatitis A virus	<i>Amanita phalloides</i>	Veno-occlusive disease	Fatty liver of pregnancy
HBV	<i>A. verna</i>	Heatstroke	Reye’s syndrome
HCV (rare, coinfection)	<i>A. virosa</i>	Chronic heart failure	Galactosemia
HDV (coinfection)	<i>A. tenuifolia</i>	Ischemia	Hereditary fructose intolerance
HEV (rare in the USA) Herpesviruses (herpes simplex virus/cytomegalovirus/varicella zoster virus/Epstein–Barr virus in immunosuppressed)	<i>A. brunnescens</i> <i>A. bisporigera</i> <i>Galerina autumnalis</i>	Myocardial infarction, pulmonary embolism, tamponade, sepsis, intraoperative hypotension, etc. Malignant infiltration	Hereditary tyrosinemia Jejunoileal bypass Autoimmune hepatitis
Yellow fever	<i>G. venenata</i>		Primary graft failure

A, *Amanita*; CHF, congestive heart failure; CMV, cytomegalovirus; EBV, Epstein–Barr virus; G, *Galerina*; HAV, hepatitis A virus; HBV, hepatitis B virus; HCV, hepatitis C virus; HDV, hepatitis delta virus; HEV, hepatitis E virus; HSV, herpes simplex virus; L, *Lepiota*; MI, myocardial infarction; PE, pulmonary embolism; VOD, vascular occlusive disease; VZV, varicella zoster virus

vasculitis, and granulomatous reactions. Categorization of these toxic reactions suggests the type and duration of exposure.

Acute APAP overdose (both deliberate and unintentional/supratherapeutic ingestion) remains one of the most common causes of ALF in the USA and UK (see ► Chap. 59, “Acetaminophen/Paracetamol”). The maximum daily approved dose may vary depending on the country, but is generally in the range of 80 mg/kg APAP for children and 3–4 g for adults. The minimum dose for toxicity from a single ingestion is generally 150 mg/kg for children and 7.5–10 g for adults [28]. Doses greater than 350 mg/kg almost always result in severe hepatotoxicity without antidotal treatment [23]. However, APAP toxicity is increasingly being recognized as a cause of ALF even when used in supratherapeutic doses, and such “therapeutic misadventures” may represent the most common cause of ALF in the USA [29]. These cases usually occur when APAP is misused in the setting of chronic pain and alcohol use or less commonly with medications that induce the cytochrome P-450 system (e.g., isoniazid [INH], rifampin, phenytoin) or in the setting of starvation (depleted glutathione [GSH] stores) [30, 31]. High aminotransferase levels are typical of such cases, with values usually peaking above 4000 U/L and sometimes above 10,000 U/L.

The metabolic activation of certain drugs by the liver into hepatotoxic intermediates is an important phenomenon in drug-induced ALF. The resultant toxic metabolites covalently bind to important macromolecular constituents of the cell and prevent normal functioning or cause necrosis of the cell. Acetaminophen metabolism (Fig. 1) serves as a pertinent example. Most of the ingested APAP is conjugated with glucuronide or sulfate and excreted as a harmless metabolite [32, 33]. In therapeutic doses, approximately 5% of APAP is oxidized by the P-450 system to *N*-acetyl-*p*-benzoquinoneimine (NAPQI), a toxic intermediate that is readily detoxified by reaction with GSH [32, 33]. An APAP overdose overwhelms the sulfation and glucuronidation pathways and drives the formation of NAPQI, detoxification of which depletes GSH stores [32, 33]. Once the binding capacity of GSH is exceeded, NAPQI

covalently binds to key hepatocyte membrane and cellular proteins and causes necrosis [22, 23].

Concurrent use of certain medications can further amplify the production of hepatotoxic intermediates by induction of the cytochrome family responsible for metabolism of the parent drug. For example, alcohol [34], INH [35], and possibly phenytoin [36] cause induction of the P-450 system, which enhances the conversion of APAP to NAPQI. In addition, alcohol inhibits the synthesis of GSH, thereby decreasing clearance of NAPQI [37]. Chronic alcohol abusers are also more likely to be malnourished and have an antecedent fasting period, which also depletes GSH stores. Thus, supratherapeutic doses of APAP in conjunction with regular alcohol use can result in elevated NAPQI levels and subsequent hepatic injury – the so-called therapeutic misadventure [38]. It is important to note that starvation, a GSH-depleted state, is an independent risk factor for a therapeutic misadventure with APAP, regardless of concurrent alcohol use. Another example of synergistic toxicity is noted in patients treated with INH and rifampin, where rifampin-induced cytochrome induction can potentiate INH hepatotoxicity [39].

Whereas APAP-induced injury is predictable and dose dependent, other drugs (e.g., valproic acid, troglitazone, amiodarone) can cause rare idiosyncratic and unpredictable hepatotoxic effects. Hypersensitivity reactions can occur with the use of phenytoin, *para*-aminosalicylate, chlorpromazine, and sulfonamides, with catastrophic results. Idiosyncratic reactions do not exhibit dose-related toxicity, and some can result in ALF with a single dose. They occur in a small fraction of susceptible individuals and are unpredictable. Patients with chronic liver disease may be at increased risk for such reactions. The formation of immunologically stimulating drug-protein complexes (neoantigens) with a resultant “innocent bystander” effect is thought to be one of the pathogenic mechanisms of injury [40].

The halogenated anesthetics enflurane, methoxyflurane, and isoflurane have uncommonly been associated with the development of toxic hepatitis, but hepatic failure is rare. They usually develop after multiple exposures to these

Fig. 1 Acetaminophen (paracetamol) metabolism

agents and are thought to be of combined toxic and allergic origin. Nonsteroidal anti-inflammatory drugs, especially sulindac and diclofenac, have also been known to cause liver disease, with an incidence of 1.1–3.7 cases per 100,000 prescriptions [41]. The macrolide antibiotics erythromycin and clarithromycin are rare causes of hepatic failure that exhibit primarily cholestasis on biopsy and, uncommonly, hepatic necrosis [42].

In a nationwide prospective study [43], the incidence of drug-induced liver injury (DILI) was investigated in a population-based cohort in Iceland. The most commonly implicated agent over the 2-year study period was amoxicillin-clavulanate with a rate of 43 DILI cases per 100,000 inhabitants. The highest risk of hepatotoxicity was associated with the use of azathioprin

(752 DILI cases per 100,000 inhabitants) and infliximab (675 DILI cases per 100,000 inhabitants).

Tetracycline demonstrates yet another mechanism of hepatotoxicity. It is known to bind hepatocyte tRNA and impair apoprotein synthesis, thereby causing triglyceride buildup in the liver. It may also cause concurrent derangements in fatty acid uptake, formation, and oxidation by hepatocytes, which can culminate in the loss of hepatic function secondary to acute microvesicular fatty infiltration [44]. Aspirin, valproic acid, amiodarone, and zidovudine are also known to cause microvesicular steatosis.

Herbal Medications

Widespread use of herbal remedies in Europe and their ever-growing popularity in the USA have

Table 3 Examples of drugs commonly implicated in acute liver failure

Acetaminophen (paracetamol)
Amiodarone
Carbon tetrachloride
Gold
Halothane
Isoniazid
Ketoconazole
Methyldopa
Monoamine oxidase inhibitors
Nonsteroidal anti-inflammatory drugs
Phenytoin
Rifampin
Sulfonamides
Tetracycline
Tricyclic antidepressants
Valproic acid

brought to light many case reports of associated hepatotoxicity. Herbs and alternative medications implicated include chaparral, gentian, germander, and senna, but they rarely result in liver failure [45]. However, in 2001 and 2002 two case reports suggesting a causal relationship between kava (a herbal supplement used for the treatment of anxiety) and ALF requiring transplantation were published [46, 47]. Twenty-four other reports of kava-related hepatotoxicity have led to a ban on kava in Switzerland and Germany. The US Food and Drug Administration (FDA) currently has the supplement on so-called MedWatch alert status. Although virtually any drug can cause acute liver injury, more common examples are listed in Table 3.

Drugs of Abuse

Severe liver injury and even hepatic failure can result from recreational drug use, including abuse of cocaine, 3,4-methylenedioxymethamphetamine (MDMA or Ecstasy), and phencyclidine, or from recreational inhalation of solvents containing toluene or trichloroethylene [48]. Hepatic failure in these cases may be the result of liver ischemia, hypoxemia, severe hyperpyrexia, rhabdomyolysis, and/or direct hepatotoxic effect.

In addition to these effects, cocaine's hepatotoxicity is thought to be due primarily to ischemia from systemic arterial vasospasm and congestive

heart failure, complicated by the occurrence of disseminated intravascular coagulation (DIC) and renal failure. The histologic pattern is both centrilobular necrosis and microvesicular steatosis. MDMA causes a syndrome similar to that of cocaine: hyperthermia, DIC, and rhabdomyolysis, complicated further by dehydration and acute renal failure. Toxic hepatitis may be immediate or delayed, and the histopathology is characterized by central and midzonal necrosis or by steatosis and eosinophilic infiltration [48]. The latter suggests an immune mechanism of MDMA hepatotoxicity, and liver transplantation has been required in some cases [49].

Chemicals

Industrial exposure to cleaning solvents containing fluorinated or halogenated hydrocarbons is a well-documented cause of hepatic necrosis, fatty infiltration, and, ultimately, ALF. Carbon tetrachloride's hepatotoxic effects, noted in the 1920s–1940s, led to its abandonment as an anesthetic and anthelmintic by the FDA, but it is still used in the production of solvents, refrigerants, and aerosol propellants. The fluorinated hydrocarbon chloroform, a potent central nervous system depressant once used as an anesthetic, has also been banned by the FDA because of its hepatotoxicity, but it is still found in industrial use.

Biologic Agents

Hepatotoxicity secondary to accidental ingestion of poisonous mushrooms has been on the rise because of popular interest in gathering and eating uncultivated mushrooms [50]. An increase in the incidence of mushroom poisoning is usually seen after periods of heavy rainfall or during the fall, when the conditions for growth are optimal. Ingestion of cyclopeptide-containing mushrooms accounts for up to 90% of mushroom-related deaths worldwide [50–54]. The genus *Amanita* is the source of most of these poisonings, especially *A. phalloides* (death cap), *A. verna* (death angel), and *A. virosa* (destroying angel). *Galerina* and *Lepiota* species can also be hepatotoxic (see Table 2). *Amanita* species are found primarily in the temperate coastal regions of the west coast of the USA, but they have also adapted to the mid-Atlantic

coast and the northeast. *A. phalloides* is the predominant hepatotoxic European mushroom. The mushroom itself has no distinct taste, smell, or appearance. Ingestion is usually followed 6–12 h later by fever, nausea, vomiting, and severe diarrhea. Renal and hepatic impairment may become evident by 24–48 h while the patient appears to be recovering clinically. However, renal failure and hepatic failure progress and tend to become severe by day 3–5, with the development of jaundice, encephalopathy, and possibly death. Liver transplantation has been carried out successfully for cases of severe *Amanita* poisoning [53]. Some *Amanita* mushrooms such as *A. muscaria* and *A. pantherina* do not contain hepatotoxins.

The cyclopeptide mushrooms contain two cyclic oligopeptide hepatotoxins: phallotoxins and amatoxins. Both are heat stable and resistant to drying [52, 54]. Phallotoxins are not absorbed from the gastrointestinal (GI) tract and therefore are not thought to play a role in the symptoms associated with human poisoning [55]. α -Amanitin is a dialyzable octapeptide that inhibits RNA polymerase II, thus interfering with mRNA synthesis [56]. The cell is robbed of its ability to produce vital structural proteins and undergoes necrosis. Tissues with a high rate of protein synthesis (liver, kidneys, brain) suffer the most damage [56]. α -Amanitin is easily absorbed from the intestinal epithelium and enters the hepatocyte via bile transport carriers [57]. It demonstrates low plasma protein binding and is cleared from plasma in 36 h [56, 57]. Sixty percent is excreted into bile and undergoes enterohepatic circulation, whereas the rest is cleared renally [55, 56] (see ► Chap. 108, “Cyclopeptide-Containing Mushrooms: The Deadly *Amanitas*” for a more detailed discussion).

Case reports of ALF caused by other noninfectious biologic agents include one published in 1994 describing ALF secondary to a sea anemone sting [58].

Nontoxic Causes

Infections

Viral hepatitis remains one of the most common causes of ALF worldwide. The majority of cases

are related to hepatitis A and E infections globally with death rates of more than 50% reported from the developing world [59, 60]. Also hepatitis B infection may lead to ALF [61]. It is unclear why ALF develops in a select proportion of the infected population, but historical review of previous epidemics reveals that this number remains surprisingly constant at approximately 0.4% [62]. The hepatocellular necrosis seen in cases of ALF caused by hepatitis A and B is thought to be due in part to a direct cytopathic effect of the virus. This mechanism is supported by the relative lack of inflammation seen in the livers of patients with viral ALF. However, the normal humoral and cell-mediated response to a massively infected liver also plays a role. One study found that the amount of hepatitis A virus (HAV) isolated from the livers of patients with HAV-associated ALF was higher than titers from patients with nonfulminant HAV hepatitis [63]. In addition, CD8⁺ T lymphocytes isolated from the livers of two patients with acute HAV infection demonstrated the ability to kill HAV-infected fibroblasts in culture, thus implying that the liver damage seen in virally induced ALF is in part cell mediated [64].

ALF secondary to HAV infection is a rare event: 0.35% of HAV infections will progress to ALF [58]. Patients have a comparatively low mortality rate (<40%) and usually recover without liver transplantation. Acute hepatitis B infection progresses to ALF in approximately 1% of infected patients, thus making hepatitis B virus (HBV) the most common viral cause of ALF [58]. Its role may be underestimated when the impact of infection with a pre-core mutant (HBV viral infection that does not produce the surface [HBsAg] or e antigen) is taken into account, as demonstrated by a study in which it was found that 35% of patients who underwent transplantation for non-A, non-B hepatitis had evidence of HBV infection by polymerase chain reaction [65]. One half to one third of patients with ALF secondary to HBV will clear HBsAg within a few days [66]; such rapid clearance is thought to be the result of a substantial immunologic response to HBV-laden hepatocytes. Interestingly, those who clear HBsAg rapidly have a more favorable prognosis (47% survival rate) than those with

continued HBsAg positivity (17% survival rate) [13]. Despite being an increasingly common cause of chronic liver disease, isolated infection with hepatitis C virus has yet to be definitively implicated in ALF [10]. Though rarely encountered in the USA, infection with hepatitis E virus in pregnant women carries a 40% mortality rate [67]. Infection with hepatitis delta virus has been implicated in about 30% of HBV-related ALF cases. In fact, the risk of ALF increases dramatically with any hepatitis virus coinfection [68, 69].

Infection with the viruses herpes simplex, Epstein–Barr, varicella zoster, cytomegalovirus, or parvoviruses occasionally causes ALF, though usually in an immunocompromised setting. Pediatric ALF in association with parvovirus B19 infection has been noted.

Case reports detailing other (rare) infectious causes of ALF have implicated *Coxiella burnetii*, *Plasmodium falciparum*, amebic abscesses, disseminated tuberculosis, and *Bacillus cereus* emetic toxin as causative agents.

Vascular Events

The liver has a unique blood supply, with the portal vein supplying 70% of total blood flow and the hepatic artery making up the remaining 30%. Disruption of either the inflow or outflow of blood can lead to ischemia, hypoxia, and ultimately ALF. Examples include prolonged hypotension (intraoperative circulatory collapse, acute myocardial infarction, acute pulmonary embolism), gram-negative sepsis and shock, congestive heart failure, veno-occlusive disease (chemotherapy- or bone marrow transplant related), Budd–Chiari syndrome, and hepatic artery thrombosis after OLT. Prolonged hypotension after an overdose of opiates or cardioactive drugs (e.g., β -receptor or calcium channel antagonists) or cardiac arrest from any agent may also produce hepatic failure. It is important to note that almost all cases of hepatic ischemia secondary to systemic hypotension are associated with very high aminotransferase levels and accompanying renal dysfunction. In contrast, patients with Budd–Chiari syndrome have aminotransferase levels between 100 and 600 U/L, although higher values are possible. Serum alkaline phosphatase is

around 300–400 U/L, whereas bilirubin is usually less than 7 mg/dL (120 μ mol/L) at onset. The disease commonly affects women and causes severe right upper quadrant pain and hepatomegaly.

Exertional heatstroke is also an important cause of ischemic ALF and is usually seen in young unconditioned patients pursuing a new exercise program in high ambient temperature and humidity. Classic (nonexertional) heatstroke occurs in patients with multiple chronic medical problems or those taking anticholinergic medications, which leaves them susceptible to disruption of temperature regulatory mechanisms or incapable of escaping the heat. Heatstroke is usually manifested by hyperthermia (core body temperature $>40.5^{\circ}\text{C}$ [104.9°F]), mental status changes (including seizures), peripheral vasodilation, and a host of metabolic derangements. Leukocytosis may also be a prominent initial feature. Acute mortality was 21% in one series [70]. Adverse drug effects (e.g., neuroleptic malignant syndrome, veno-occlusive disease) can play a role in ischemic ALF. Disruption of sinusoidal blood flow by metastatic cancer has also been described as a cause of ALF. Gastric, breast, and oat cell carcinomas have been implicated, as have leukemia, carcinoid syndrome, and amyloidosis.

Metabolic and Other Causes

ALF can occur even without large-scale hepatic necrosis, as demonstrated by patients who suffer from liver failure secondary to acute fatty liver of pregnancy (AFLP), Reye's syndrome, or a fulminant manifestation of Wilson's disease. ALF as an initial feature of Wilson's disease is rare but carries a very high mortality rate without liver transplantation. A relatively low serum alkaline phosphatase level and a disproportionately elevated bilirubin level (up to 30 mg/dL [$513\ \mu\text{mol/L}$]) characterize such a manifestation. The serum copper level is usually elevated.

Whereas loss of hepatocyte function in Wilson's disease is secondary to hepatic copper overload, AFLP results in ALF from an inherited defect in mitochondrial beta oxidation of long-chain fatty acids [71]. AFLP usually occurs in the third trimester and may be associated with

preeclampsia. Serum aminotransferase levels usually stay below 1000 U/L unless the HELLP syndrome (hemolytic anemia, elevated liver function tests [LFTs], and low platelet count) is present. Infant mortality is high in either case.

Reye's syndrome has a similar pathogenesis and can be seen in pediatric cases with an antecedent viral illness treated with aspirin. Other rare metabolic anomalies that can cause ALF are listed in Table 2. Rarely, autoimmune hepatitis and primary graft failure after liver transplantation will be manifested as ALF.

Diagnosis and Complications

ALF is the common final pathway of a variety of insults, and thus the features remain remarkably similar regardless of the etiology. Nonspecific flu-like symptoms, including fatigue, nausea, loss of appetite, and malaise, are the initial symptoms in previously healthy patients. These symptoms are followed by jaundice and then alteration of mental status with rapid progression to coma. Other helpful signs on physical examination include decreased or absent dullness to percussion in the right upper quadrant, indicative of reduced hepatic mass secondary to necrosis. Feter hepaticus is usually present, but recognition of this condition is somewhat subjective. Ascites is more common with subfulminant hepatic failure. Stigmata of chronic liver disease do not support a diagnosis of ALF as per the classic definition. Low blood pressure (decreased systemic vascular resistance) and hypothermia may also be evident. Laboratory derangements include high serum aminotransferase levels, low blood glucose levels, and a prolonged prothrombin time. Metabolic acidosis with respiratory compensation may be evident on arterial blood gas measurement. Complications seen in the course of the illness include cerebral edema; renal failure; cardiovascular, pulmonary, and metabolic derangements; and problems with infection, GI bleeding, and malnutrition. Multiorgan failure is commonly encountered. There is an inverse relationship between the presence and number of complications and patient survival. The diagnosis is often

delayed without an appropriate index of suspicion, and such delay can have catastrophic implications in as much as early diagnosis and appropriate management are important to preserve the ability of these patients to receive a transplant should it become necessary. Overall, the presence of coagulopathy in a jaundiced patient with an altered mental status remains the hallmark of ALF.

Coagulopathy

Coagulopathy is universally present and can be the first sign of impending liver failure. It is due mainly to decreased hepatic synthesis of clotting factors [72]. Therefore, serial measurements of prothrombin time and factor V levels have prognostic significance and provide the best measure of whether hepatic function is improving or deteriorating. DIC and local fibrinolysis do occur in ALF, and though not usually severe, they can be exacerbated by infection or by the infusion of activated clotting factors [73]. Administration of fresh frozen plasma *in the absence of bleeding* is not recommended because it has not been shown to be of value [72] and will alter the prothrombin time, thus hindering patient assessment. Platelet function is altered (prolonged capillary bleeding time), and thrombocytopenia secondary to bone marrow suppression, hypersplenism, and intravascular consumption is present in up to two thirds of patients [74]. If invasive procedures are necessary, correction of coagulation abnormalities may be relevant and needed.

Encephalopathy

Unlike the conditions observed in chronic hepatic disease, the encephalopathy associated with ALF can be manifested as agitated delirium, paranoid behavior, or even a psychotic state. Seizures may occur. The initial stages of encephalopathy are secondary to bilateral forebrain dysfunction, with the latter being secondary to brainstem impairment. Table 4 delineates the grading system used for acute hepatic encephalopathy; the

Table 4 Progressive stages of hepatic encephalopathy

Stage	Level of consciousness	Neuromuscular changes	Behavioral/intellectual changes
I	Reversal of sleep pattern	Mild asterixis	Euphoria/depression
	Mild confusion	Impaired handwriting	Short-term memory lapses
II	Slow responses	Asterixis/ataxia	Inappropriate behavior
	Increasing drowsiness	Slurred speech	Loss of time/amnesia
III	Disorientation	Rigidity/spasticity	Stuporous/incoherent
	Somnolence	Loss of continence	Marked confusion/paranoia
IV A/B	Comatose	Decorticate/decerebrate	Comatose
	A: responds to pain	Hyperreflexic	
	B: no response to pain		

presence of stupor or coma portends a poorer prognosis. Although the exact pathogenesis remains elusive, the encephalopathy is reversible and thought to be metabolic. Structural changes such as those seen with Alzheimer's disease are not part of the syndrome. It is postulated that elevated levels of neuroactive humoral substances secondary to decreased hepatic clearance cause the observed mental status changes. It is important to note that the blood–brain barrier is disrupted in ALF, and this increased permeability makes it unnecessary for a substance to be present in greater than normal concentration in plasma to affect cerebral function. In addition, with the blood–brain barrier demonstrating marked regional differences in permeability, the concentration of potentially encephalopathic agents at critical subcellular sites may be more important than their concentration in cerebrospinal fluid or plasma [75]. Studies have implicated increased GABAergic (transmitting or secreting γ -aminobutyric acid) tone, mediated by an endogenous benzodiazepine-like ligand, as a cause of the hepatic encephalopathy seen in ALF [76]. Treatment with flumazenil (a benzodiazepine receptor antagonist) has been shown to temporarily improve the coma grade of patients suffering from this syndrome.

Cerebral Edema

Cerebral edema with resultant increased intracranial pressure (ICP) is a common complication of ALF, with up to 81% of patients demonstrating signs of increased ICP during the course of the

illness [77]. Although it is a distinct entity, its signs and symptoms may be missed because of the presence of concurrent encephalopathy – often with deadly consequences. Herniation of the cerebellar tonsils or the uncinat process of the temporal lobe is a significant cause of death, and evidence of herniation is present in up to 25–30% of patients with cerebral edema [78].

The causative metabolic and pathophysiologic derangements that lead to cerebral edema have yet to be fully elucidated. Research indicates a complex interplay among vasogenic (alterations in blood flow), cytotoxic (loss of osmoregulation), and hydrocephalic (extracellular expansion) factors. Even though earlier histologic studies of the brain revealed no abnormalities [79], more recent data have found alterations in cell membrane integrity and blood–brain barrier permeability [80, 81], changes probably responsible for the increased water content and weight of the brain. Although patients with cirrhosis rarely have cerebral edema, a marked decrease in intracranial blood flow has been noted in those with acute or chronic encephalopathy [82]. This decreased blood flow, along with the systemic hypotension commonly found in ALF (see the next section) and the increased ICP secondary to cerebral edema, predisposes the brain to ischemic injury. Cerebral perfusion pressure (CPP = mean arterial pressure [MAP] – ICP) below 40–50 mmHg is associated with ischemic brain injury and can have permanent consequences, even if the liver recovers fully. A persistent and refractory perfusion pressure of less than 40 mmHg precludes transplantation [83]. Signs of increased ICP are noted in Table 5. Because they are manifested

Table 5 Signs of increased intracranial pressure in fulminant hepatic failure

Brainstem respiratory pattern, apnea
Decerebrate posturing/rigidity
Focal seizures
Increased muscle tone
Loss of oculovestibular reflex
Myoclonus
Unequal, fixed, or abnormally reacting pupils

only late in the course of events (i.e., only if ICP is greater than 30 mmHg), these signs cannot be used to gauge the need for therapeutic intervention.

Although computed tomography (CT) scans are often used to exclude intracerebral hemorrhage as a cause of a sudden change in mental state, their static nature in this rapidly evolving syndrome makes them unsuitable as a management guide. ICP monitoring provides reliable data on which treatment decisions can be made, and placement of a subdural or epidural transducer is indicated in patients being considered for transplantation. Patients should be transferred to a transplant center early in the course of the disease; transportation after the onset of cerebral edema and coma is fraught with danger because even positional changes can raise ICP with disastrous consequences. Factors that tend to increase ICP are noted in Table 6. Even without herniation, cerebral edema remains the most common cause of death in ALF.

Cardiovascular Derangements

Systemic hypotension occurs in most patients with ALF and is mediated in part by decreased systemic vascular resistance (resembling septic shock), bacteremia, hemorrhage, hypovolemia, and increased interstitial edema (increased capillary permeability) and ICP. An etiology is not found in up to 60% of cases [84]. Nearly all patients with stage IV encephalopathy suffer from arrhythmias. Although sinus tachycardia is most common, the spectrum includes heart block and cardiac arrest. ST segment and T wave

Table 6 Factors that increase intracranial pressure

Arterial hypotension
Coughing
Fever

Seizures
Severe hypoxemia
Shivering
Sneezing
Trendelenburg position
Valsalva maneuver
Vasodilatory agents
Vomiting

changes may occur. Exacerbating factors include hypoxemia, acidosis, hyperkalemia, and cerebral edema [85].

Renal Failure

Renal impairment is present in up to 75% of patients with ALF [86] more frequent in the elderly and in patients with APAP-induced ALF [87] and includes prerenal azotemia, hepatorenal syndrome, and acute tubular necrosis. Hepatorenal syndrome is a diagnosis of exclusion and is characterized by a serum creatinine concentration greater than 1.5 mg/dL (133 μmol/L), a urinary sodium concentration less than 10 mEq/L (without taking diuretics), lack of improvement with volume expansion, and a bland urinary sediment [88]. Systemic hypotension and splanchnic vasodilation (probably nitric oxide driven) activate the renin-angiotensin axis, with resultant renal vasoconstriction. Renal vasoconstriction leads to a drop in renal perfusion pressure, which is reflected by a decreased glomerular filtration rate and increased sodium retention (causing ascites and edema). The presence of oliguric renal failure portends a poorer prognosis [89]. Renal

impairment may also occur secondary to the toxic effects of substances that caused the ALF, such as APAP, hepatotoxic mushrooms, hydrocarbons, and MDMA.

Pulmonary and Ventilatory Derangements

Up to 30% of patients will have evidence of pulmonary edema during the course of their illness, especially those with cerebral edema [90, 91]. Accurate determination of volume status by pulmonary artery pressure monitoring has been shown to improve survival [92]. Intrapulmonary arteriovenous shunting, peripheral capillary blockage with cellular debris from necrotic hepatocytes, or low-grade DIC, interstitial edema, and increased vasomotor tone ultimately lead to lactic acidosis secondary to anaerobic metabolism, which can exacerbate cerebral ischemia [93, 94]. The use of NAC and proctacyclin to improve tissue oxygenation remains experimental and controversial [94–96].

Infection

Metabolic inhibition of polymorphonuclear leukocytes, decreased opsonization, and impaired cell-mediated and humoral immunity greatly predispose patients with ALF to bacteremia and fungemia [58, 97]. Patients have increased risk of infection secondary to multiple indwelling catheters, antacid therapy, artificial ventilation, coma, and treatment with broad-spectrum antibiotics. Skin flora organisms (*Staphylococcus* and *Streptococcus* spp.) are most commonly isolated in patients with ALF [98]. In a prospective study of 50 patients with acute liver failure, infection was suspected in 45 patients and proved by positive cultures in 40 [99]. However, prophylactic antibiotic treatment has not been shown to improve survival [100].

Gastrointestinal Bleeding

The severe coagulopathy seen with ALF predisposes patients to hemorrhage from the GI tract,

with the upper GI tract being the most frequent site of bleeding [101]. Diffusely hemorrhagic gastritis, esophagitis, and nasogastric tube trauma are common etiologies. Exacerbating factors include tissue hypoxia from hypotension, microcirculatory disruption, and hypoxemia, along with DIC, bacteremia, and ventilator-associated platelet dysfunction. Large episodes of bleeding lead to further hypotension and tissue (including cerebral) hypoxia and can cause worsening renal failure as a result of prerenal azotemia, as well as exacerbating hepatic encephalopathy. Despite the numerous risk factors for hemorrhage, infusion of fresh frozen plasma or platelets for correction of coagulopathy or thrombocytopenia is not indicated in the absence of bleeding.

Metabolic Derangements

Electrolyte and acid–base disturbances are common in ALF and can exacerbate encephalopathy and cause arrhythmias. Despite renal retention of sodium, hyponatremia occurs frequently and is due to impaired renal free water excretion. Hypokalemia is present and can be profound; etiologies are multiple and include renal losses (secondary to hyperaldosteronism and sodium retention, as well as secondary to hydrogen ion resorption to compensate for respiratory alkalosis), GI losses (decreased intake, vomiting), and iatrogenic causes (e.g., diuretics, nasogastric tube suctioning, lactulose use). Hypophosphatemia, hypomagnesemia, and hypocalcemia can also occur. Complex acid–base disturbances with multiple processes at play are seen – respiratory alkalosis as a result of spontaneous hyperventilation is commonly present early in the course of the disease. However, with disease progression and depression of the central respiratory drive secondary to edema or circulating toxins, respiratory acidosis can develop. Hypokalemia is associated with metabolic alkalosis, whereas tissue hypoxia and massive hepatic necrosis give rise to metabolic acidosis with elevated levels of lactic acid, free fatty acid, and other organic acids. The presence of lactic acidosis is a poor prognostic indicator. Impaired glucose release, loss of glycogen

reserves, and decreased gluconeogenesis are in combination responsible for severe hypoglycemia (blood glucose <40 mg/dL [2.2 mmol/L]) in up to 40% of patients. Decreased hepatic metabolism of insulin resulting in inappropriately elevated plasma insulin levels also plays a pathogenic role. If unrecognized and untreated, the fall in blood glucose can be rapid and may lead to irreversible brain injury.

Diagnostic Studies

Laboratory and radiographic testing should be performed to confirm the diagnosis, elucidate the etiology of ALF, evaluate for the presence of complications, and obtain data necessary for management, prognostication, and preparation of the patient for possible liver transplantation. See Table 7 for a list of recommended initial diagnostic tests for ALF. Serum glucose should be monitored frequently (every 2 h), and other parameters such as electrolytes, hematocrit, and arterial blood gas should be monitored at least three times daily. Coagulation parameters and LFTs are usually checked twice a day. Further testing, such as tomographic studies of the head to rule out intracerebral hemorrhage or cerebral edema as a cause of acute worsening of mental status, is performed as clinically indicated.

Treatment

Because of the unpredictable nature of the disease, the risk of acute decompensation, and the severity of the illness/complications, patients with ALF should be managed in an ICU setting, preferably at a liver transplant center. Hospitals without liver transplant programs should transfer patients with ALF to such transplant centers as soon as possible because increased ICP and severe coagulopathy make transfer later in the course of the disease much more hazardous. Uncompromised ICU support is necessary to give these patients the best chance for survival. Specific treatment strategies for commonly encountered complications are discussed in the following sections.

Table 7 Initial diagnostic testing in fulminant hepatic failure

Parameter	Rationale
Electrolytes and minerals	Imbalances are common; can cause arrhythmias, worsen encephalopathy. Hypophosphatemia is common in acetaminophen overdose
BUN/creatinine	Renal failure is typical; affects management and prognosis. Etiology (e.g., toxic effect of ingested substances) may alter therapy (e.g., hemodialysis)
Glucose	Hypoglycemia is common; can have permanent neurologic sequelae
CBC with platelets	Assess for sepsis (leukocytosis), GI bleeding (anemia), and risk of hemorrhage (thrombocytopenia)
Liver profile	Assess degree of damage, follow course of illness
Coagulation profile	Prognostic indicators (PT, factor V level), assess risk of hemorrhage
Arterial blood gases	Prognostic significance (lactic acidosis), derangements common
Blood group	Preparation for transplantation; type and crossmatch in anticipation of bleeding
Toxicology, virology, autoimmune panel, ceruloplasmin, medication history	Etiology affects management (e.g., NAC for acetaminophen, charcoal for <i>Amanita</i>) and prognosis. Refer to Table 2 for various etiologies of ALF
Blood and urine cultures	Surveillance for sepsis; aggressive treatment warranted if positive
ECG	May affect management, preparation for transplantation
Chest radiograph	Sepsis surveillance; evaluate for ARDS, pulmonary edema
Abdominal ultrasound	Evaluate for vascular thrombosis, preparation for transplantation

(continued)

Table 7 (continued)

Parameter	Rationale
Pulmonary wedge pressure	Assess volume status if hypotension present
Intracranial pressure	Assess ICP if stage III–IV encephalopathy present. Cerebral edema is the most common cause of death

ARDS, adult respiratory distress syndrome; BUN, blood urea nitrogen; CBC, complete blood count; ECG, electrocardiogram; ALF, fulminant hepatic failure; GI, gastrointestinal; ICP, intracranial pressure; NAC, N-acetyl-L-cysteine; PT, prothrombin time

Coagulopathy

Decreased synthesis of coagulation factors is a direct reflection of hepatic dysfunction and can be used as a prognostic indicator. Therefore, prophylactic correction of coagulopathy in a non-bleeding patient is not recommended because it does not influence mortality, can interfere with assessment of disease severity, and may predispose the patient to volume overload and worsening cerebral edema [24, 102]. Blood products (fresh frozen plasma or, rarely, recombinant human factor VIIa) may be used to correct coagulopathy in cases of active hemorrhage/GI bleeding and for invasive procedures [103].

Encephalopathy

Encephalopathy is part of the definition of ALF and as such plays a major role in the patient’s clinical findings and course. Patients with grade 4 encephalopathy should be intubated for airway protection. Standard treatment with lactulose enemas or lactulose via a nasogastric tube, 30 mL three to four times a day, is instituted in an attempt to decrease the amount of nitrogenous waste (in the form of ammonia) absorbed from the gut lumen. However, new evidence suggest that the use of polyethylene glycol (PEG) may be superior to lactulose in the treatment of encephalopathy in cirrhotic patients [104] (Grade I recommendation). Oral neomycin has traditionally been added if the encephalopathy is difficult to control, but it has possible nephrotoxic and ototoxic side effects. Modern drugs of choice instead are

metronidazole, 250–500 mg two to three times a day, aminopenicillins, 2–4 g/day, or vancomycin, 1–2 g/day. More recently it has been shown that the minimally absorbed oral antibiotic rifaximin maintains remission from hepatic encephalopathy more effectively than placebo [105] (Grade I recommendation).

Cerebral Edema

Cerebral edema (leading to elevated ICP, ischemic/hypoxic brain injury, and brainstem herniation) is the most common cause of death in ALF and is present in up to 80% of patients with grade 4 encephalopathy [106]. Given the deadly consequences of unrecognized cerebral edema and the difficulty in diagnosing it clinically, an epidural ICP monitor should be placed in all patients with grade 4 encephalopathy. This procedure has a 4% morbidity (infection, bleeding) rate and a 1% mortality rate and is thus safer than placement of a subdural, parenchymal, or intraventricular catheter [107]. Coagulopathy should be addressed before placement of an ICP monitor, and head CT should be considered to rule out other causes of acute mental status changes such as intracranial hemorrhage. The aim is to keep ICP lower than 20 mmHg and CPP ($\text{MAP} - \text{ICP} = \text{CPP}$) higher than 50 mmHg [2] (Grade III recommendation).

Elevated ICP can be treated with mannitol boluses (0.5–1 g/kg to achieve a plasma osmolality between 310 and 325 mOsm/kg) [108]. Clinicians should be vigilant for signs of volume overload with mannitol use; concurrent ultrafiltration or other dialysis methods may be needed to avoid hypervolemia. In addition, patients should be stimulated as little as possible because agitation can increase ICP. Sedatives should be used in the lowest dose possible so that the degree of encephalopathy can continue to be monitored. Short-acting drugs such as propofol should be used [109]. Elevating the head of the bed can decrease ICP, but it also causes CPP to fall and leads to paradoxical increases in ICP when elevation is above 30° [102]. In the absence of ICP monitoring, the head of the bed should be elevated 10–20° (Grade III recommendation). The use of positive

end-expiratory pressure during ventilation can also worsen cerebral edema [110]. Dexamethasone has been proved to be ineffective as treatment of cerebral edema and should therefore not be used [111]. Hyperventilation to lower PCO₂ has not been shown to be beneficial [102].

Renal Failure

Most patients with ALF have evidence of acute kidney injury (AKI), the presence of which carries a grave prognosis. Treatment is centered on prevention: the use of nephrotoxic drugs (e.g., aminoglycosides) is avoided, intravascular volume is optimized with judicious use of colloid supplementation in the form of packed red cells or salt-poor albumin, and MAP is maintained as close to normal as possible. A high index of suspicion should be entertained for AKI secondary to the direct toxic effects of substances such as APAP or hepatotoxic mushrooms. Although urinary sodium values can be used to guide therapy, the blood urea nitrogen concentration may underestimate the renal dysfunction because of decreased hepatic urea production.

Infection

A decline in renal function or worsening/recalcitrant encephalopathy may be the first clues to an untreated infection in patients with ALF. Thus, a high index of suspicion must be maintained, with a low threshold for diagnostic testing (including blood, urine, and sputum cultures, chest x-ray, paracentesis) and empirical broad-spectrum antibiotic/antifungal coverage. The most common sites of infection include the respiratory system, the urinary tract, and blood [112]. Although prophylactic antibiotic use has not been shown to be helpful, a surveillance culture regimen with aggressive directed therapy if an infection is suspected is recommended.

Gastrointestinal Bleeding

All ALF patients deserve stress ulcer prophylaxis with oral/IV proton pump inhibitors. Sucralfate

may also be used. Coagulopathy and thrombocytopenia should be corrected in patients with bleeding from the GI tract, but not prophylactically. Large GI bleeds are investigated and treated endoscopically. If variceal bleeding is suspected, treatment with an octreotide IV drip should be initiated without delay for endoscopic confirmation.

Metabolic Derangements

The various metabolic derangements seen in ALF have been detailed earlier. As part of supportive ICU care, electrolytes should be checked and corrected at least twice a day. Hypoglycemia is common in ALF and needs closer attention. Hypertonic glucose solutions should be administered as an IV drip to keep blood glucose levels above 65 mg/dL (3.6 mmol/L). Restriction of free water may be needed to treat hyponatremia, but hypertonic saline is rarely required. Acetaminophen-induced ALF without renal impairment is commonly associated with hypophosphatemia, which may require therapy [113].

Nutrition

A diet low in protein is advocated for patients with ALF who are able to tolerate oral intake (grade 1–2 encephalopathy). Enteral low-protein tube feeding should be considered early in the course of the disease for the rest of the patients to prevent unnecessary catabolism to preserve muscle bulk and immune function [114] and to optimize management before possible liver transplantation. Tube feeding should be administered into the distal duodenum/jejunum if possible to decrease the risk of aspiration.

Specific Antidotes

Two of the most common conditions for which specific treatment of ALF is available are APAP overdose and *Amanita* mushroom poisoning. Other rare treatable etiologies include AFLP (treated by delivery), shock liver (treated by

optimizing hemodynamic status), acute Budd–Chiari syndrome (treatment considerations include transjugular intrahepatic portosystemic shunt versus surgical decompression versus thrombolysis), herpesvirus infection (treated with acyclovir), and autoimmune hepatitis (treated with steroids).

► [Chapter 59, “Acetaminophen/Paracetamol”](#) provides detailed discussion on the treatment of APAP overdose, but in general, if severe acetaminophen toxicity is suspected, intravenous NAC should be administered without delay. Activated charcoal (1 g/kg) may decrease APAP absorption if administered within 1 or 2 h of ingestion. In most countries, the plasma APAP concentrations are determined in all suspected cases and values plotted against the established nomogram to determine whether NAC administration is indicated. However, in Denmark the use of a nomogram is not recommended. All patients suspected of APAP poisoning are treated with NAC immediately after hospital admission. Information from patients with suicidal behavior about time of ingestion are often unreliable which may lead to a wrong decision about NAC treatment if a nomogram is used [115]. However, those with liver injury and suspected acetaminophen toxicity, even in the absence of detectable APAP, should receive NAC treatment.

Mushroom poisoning can be established by isolating α -amanitin in serum or urine by radioimmunoassay. Its enterohepatic circulation can be interrupted by using repeated doses of activated charcoal, and possibly forced diuresis can increase the rate of renal clearance of the toxin (see ► [Chap. 108, “Cyclopeptide-Containing Mushrooms: The Deadly *Amanitas*”](#)). Silibinin and IV penicillin G have been used as specific therapies for *Amanita* poisoning. Silibinin is thought to impede the uptake of α -amanitin by hepatocytes and may be efficacious up to 48 h after the ingestion of toxin [57].

Prognosis

Patients with ALF can be broadly divided into two categories – those who have enough hepatic reserve left to survive and recover with optimal

medical care and those who have sustained an irreversible hepatic insult and will die despite supportive care. OLT is the best available option for the second cohort; it is not appropriate therapy for the first group. The difficulty lies in accurately categorizing patients into one of these two groups and doing so in a timely manner, before the complications associated with ALF preclude OLT as a therapeutic option. Overall, current estimates reveal that only about 10% of patients with ALF receive a transplant [106]. Posttransplant survival rates have been estimated at 55% to 75% [116], although rates may improve to over 90% with stringent selection criteria [108]. As noted earlier, ALF without OLT is associated with very high mortality rates, and survival remains dismal for those who are listed for transplantation but do not receive an organ in time. In general, transplantation is recommended if the patient’s survival rate is estimated to be below 20%.

**A number of prognostic indicators have been identified to help clinicians predict the severity of ALF and identify patients who would benefit from transplantation. It is well known that the etiology and the presence/number of associated complications can influence the survival rate. Time from the onset of jaundice/symptoms to the development of hepatic encephalopathy can also predict a survival difference in certain cohorts, as mentioned in the discussion in the [“Definitions”](#) section of this chapter. The severity of encephalopathy at admission is inversely related to survival in patients with acetaminophen toxicity and acute liver failure [25]. Although age younger than 10 or older than 40 years has been shown to be a poor prognostic indicator in older studies, it did not play a role in survival rates from a more recent US series [25]. Liver histology is not routinely used because it has not been proved to accurately predict outcome [117].

The aforementioned variables (age, etiology, degree of encephalopathy, time to onset of symptoms, etc.), though identifying survival trends, do not allow for an accurate prediction of the need for transplantation. To better identify high-risk patients who would require liver transplantation

Table 8 King’s College Criteria (indications for transplantation)

Acetaminophen toxicity	Non-acetaminophen toxicity
pH <7.3 (irrespective of other factors)	PT >35 s (US units) or INR >7.7 (irrespective of degree of encephalopathy)
<i>Or all three of the following:</i>	<i>Or any three of the following:</i>
Grade III–IV encephalopathy	Age <10 or >40 year
PT >100 s	Unfavorable etiology (non-A non-B hepatitis, idiosyncratic drug reaction, halothane hepatitis, Wilson’s disease)
Serum creatinine >3.4 mg/dL (300 μmol/L)	Serum bilirubin >17 mg/dL (300 μmol/L)
	Time from jaundice to encephalopathy >7 days
	INR >4

INR, international normalized ratio; PT, prothrombin time

for survival, a statistical model was developed by investigators at King’s College in London. From a cohort of 588 patients managed medically between 1973 and 1985, a multivariate analysis was performed on a number of biochemical and clinical variables and their relationship to mortality, and recommendations for transplantation were based on the results. The negative prognostic indicators (also known as King’s College Criteria) for which transplantation is recommended are noted in Table 8 [1].

The King’s College Criteria have been validated at other centers and in a prospective manner. Patients with ALF but without APAP toxicity demonstrated a mortality rate of 80% with the presence of any one of the negative prognostic indicators; mortality rose to 95% with the association of three negative prognostic factors. Severe acidosis (pH <7.3) in patients with APAP toxicity was associated with a mortality rate of 95%. Excluding acidosis, the presence of any other adverse characteristic in this population resulted in a mortality rate of at least 55%. These mortality rates are much higher than those associated with liver transplantation; thus, patients with even one negative prognostic indicator should be considered for listing [1]. A subsequent meta-analysis confirmed that the King’s College Criteria have

clinically acceptable specificity but more limited sensitivity [118].

Other predictive models have been developed to assess the degree of liver injury and identify patients who need liver transplantation for survival. Acute Physiology and Chronic Health Evaluation (APACHE) II scores were similar to the King’s College Criteria in identifying those needing transplantation, but patients were recognized earlier in a few cases [119]. Serum Gc-globulin and plasma factor V levels have been used independently to predict outcome; however, they are specialized laboratory tests that may not always be available and have not been shown to be any better than the King’s College Criteria [120]. Factor V levels vary by age; transplantation is recommended for a factor V level less than 20% in ALF patients younger than 30 years or for a factor V level less than 30% for those older than 30 years [121]. However, patients have recovered without transplantation with factor V levels less than 10%, in our experience. Also measurement of arterial blood lactate may improve the speed and accuracy of selection of appropriate candidates for OLT. In a single-center study, the prediction of non-surviving APAP-induced ALF patients using lactate was similar to KCH criteria but identified them earlier [122]. Although early recognition of patients most likely to benefit from transplantation is important, it is equally important to recognize those in whom liver transplantation is contraindicated (Table 9).

Future Trends

The scarcity of donor livers has led to investigation of alternatives to transplantation not only for patients who need temporary support while their native liver recovers from the acute insult but also for those who need a “bridge” to transplantation. A number of novel and promising approaches have been tried, including auxiliary liver transplantation, liver dialysis systems, artificial hepatic assist devices, and xenotransplantation. All are in the research phase and need further study with controlled clinical trials to delineate their safety

Table 9 Absolute contraindications to liver transplantation

Severe cardiac or pulmonary disease
Severe pulmonary hypertension (PA systolic pressure ≥ 60 mmHg)
Adult respiratory distress syndrome ($\text{FiO}_2 > 0.6$)
Uncontrolled intracranial hypertension/irreversible brain damage
HIV infection/AIDS
Systemic sepsis
Extrahepatic malignancy
Portal and mesenteric vein thrombosis
Active alcohol or drug use
Severe psychological disorders
Inability to understand/commit to the procedure and the lifetime of responsibility it entails

AIDS, acquired immunodeficiency syndrome; HIV, human immunodeficiency virus; PA, pulmonary artery

and efficacy. Liver dialysis systems have not met with great success. Hemodialysis, charcoal hemoperfusion, and blood and plasma exchange have been tried without any demonstrated alteration in outcome [102].

Auxiliary liver transplantation involves placement of a partial liver graft in either a heterotopic location or a space provided by partial hepatectomy. Although the graft is not large enough to sustain the patient independently, it provides enough support to allow the native liver to recover. No indications for auxiliary transplantation have been established, and it still requires a donor source in the presence of the current organ shortage. However, a number of patients have recovered when auxiliary grafting is used as a bridge, thus obviating the need for whole-organ transplantation and lifelong immunosuppression [123].

Early experiments of extracorporeal perfusion with animal organs led to the idea of hybrid artificial devices that would combine the efficacy and compatibility of a human liver with the ease of hemodialysis. These hybrids, known as extracorporeal liver assist devices (ELADs) and bioartificial livers, incorporate living human hepatocytes embedded around a nest of hollow fiber capillaries housed in a cartridge through which the patient's blood is transfused [124]. The device functions as an extracorporeal

artificial liver, with the living hepatocytes performing all the functions of the native liver across the semipermeable capillary membrane. Recent research has focused on trying to reproduce the hepatic architecture in the ELAD cartridge, identifying the optimal hepatocyte mass needed to provide the best results, and determining the ideal perfusion time necessary for a favorable outcome. The most extensively studied nonbiological device is the molecular adsorbent recirculating system which has shown some evidence in case series to improve biochemical parameters [125].

The kidney carries out a number of crucial roles in the regulation of homeostasis. In addition to maintaining normal body volume, electrolyte concentration, and excretion of waste substances, kidneys regulate blood pressure and red cell carrying capacity and carry out a host of other functions. It is therefore not surprising that even small acute deteriorations in renal function lead to significant morbidity and mortality [1–3]. Acute kidney injury (AKI) is a common finding in hospitalized patients, with an incidence of 3–20% depending on the population studied; the incidence of AKI increases to 16–67% in intensive care units and appears to be growing [2, 3].

One of the most important roles of the kidney is organic solute excretion, including the excretion of many drugs, toxins, and their metabolites. As these solutes are excreted by the kidneys, they may reach high concentrations within the renal tubules; thus, any adverse effect these compounds exert upon cellular tissue may be magnified in the kidneys compared to other organs [4]. Drugs and toxins are frequently implicated as contributing to development of AKI – they may play a primary role or a synergistic role with other processes [5–9]. Because the kidney plays a central role in the elimination of many solutes, development of AKI from any cause may conversely worsen the severity of a multitude of poisonings through decreased excretion of toxins. Given the frequency and severity of AKI, as well as this unique importance of AKI to the poisoned patient, a comprehensive knowledge of mechanisms,

complications, and management of AKI is important to the practice of medical toxicology.

Review of Renal Anatomy and Physiology

In normal physiology, the kidneys play a key role in maintaining normal homeostasis through solute excretion, electrolyte reabsorption and excretion, volume regulation, control of blood pressure, and a number of other functions. Despite a size of about 1% of total body mass, the kidneys receive about 20% of cardiac output. The kidneys have an extensive microcirculation; after originating through the renal arteries which arise from the abdominal aorta, the majority of renal blood flow (RBF) is directed to afferent arterioles, which in turn lead to capillaries in the renal cortex. These capillaries, known as glomerular capillaries, deliver high blood flow to the microarchitecture of the kidney; it is through this high-pressure system that a large portion of the cardiac output may be filtered through the kidneys, allowing for separation of waste products and excess fluid [10].

The kidneys are comprised of functional units called nephrons, each of which is capable of hormonal regulation as well as reabsorption and secretion of solutes and water. An average adult will have approximately one million nephrons, although this number may vary widely [11]. Nephrons are comprised of the glomerulus, the proximal convoluted tubule, the loop of Henle, the distal tubule, and the connecting tubule. The glomerulus is a network of capillaries enclosed by a layer of endothelial cells, which in turn is enclosed in Bowman's capsule, an epithelial layer of cells. As blood flows through the renal arteries, it is eventually diverted to small arterioles known as the afferent arterioles. From the afferent arterioles, glomerular capillaries arise, flowing through the glomerulus to arterioles known as the efferent arterioles. The afferent and efferent arterioles constrict and dilate in response to local and systemic hormonal factors such as angiotensin II, vasopressin, prostaglandins, and sympathetic innervation; this allows for tightly controlled regulation of renal blood flow (RBF) [10].

Blood flowing through glomerular capillaries is filtered through hydraulic pressure across the basement membrane of the glomerulus into an area known as Bowman's space. The pressure in the glomerular capillaries and Bowman's space, as well as the oncotic pressure of blood in the glomerular capillaries, provides the driving gradient for filtration of what will become the urine into Bowman's space. On average, adult kidneys produce around 150 l of filtrate; more than 99% of this is reabsorbed, producing about 1–2 l of urine daily [10, 12].

As filtrate flows into the glomerulus, it passes through the renal tubules and becomes known as luminal fluid. The proximal convoluted tubule acts as the "workhorse" of the nephron to reabsorb desired solutes (such as sodium, glucose, and a variety of others); the proximal tubule also secretes waste products ("uremic toxins," acid, and others) into the tubular lumen. It should be noted that the proximal tubule reabsorbs and secretes many organic solutes, including various drugs and toxins [13]. For this reason, the proximal tubule is often the most affected portion of the kidney by various toxic substances and a frequent site of kidney damage by nephrotoxins [10, 12, 13].

The loop of Henle serves to further reabsorb electrolytes and fluid and, through a mechanism known as the "countercurrent mechanism," generates a gradient which is used to concentrate the urine. The distal tubule and connecting tubule further act upon the electrolyte composition of the luminal fluid by reabsorbing and secreting various electrolytes, excreting additional acid, and determining the ultimate degree of concentration of the urine. Urine is then emptied into the renal pelvis, which is drained by the ureters into the bladder [12].

Kidney function is usually estimated by the glomerular filtration rate (GFR), the volume of urine filtered across the glomerulus per unit time. A normal GFR in children above the age of infancy and young adults is approximately 120 mL/min per 1.73 m² of body surface area; this decreases over time as aging progresses [10, 14]. GFR is directly proportional to RBF; the regulation (known as renal autoregulation) of

GFR, therefore, is carried out in large part by varying RBF through constriction and dilation of the afferent and efferent arterioles. Mechanistically, this regulation is carried out through responses to tubular fluid flow and composition (known as tubuloglomerular feedback) as well as arteriolar smooth muscle stretch receptors causing vasoconstriction and vasodilation of renal blood flow in order to maintain near-constant glomerular capillary pressure (known as the myogenic mechanism) [10]. In the setting of acute kidney injury, GFR cannot be estimated well from static values alone; functional measures, such as urinary output, are of more utility [3].

AKI: Definitions and Clinical Importance

AKI is characterized by reduced renal function over a period of hours to days with retention of organic waste solutes. As a consequence of reduced kidney function, fluid, electrolyte, and acid–base derangements may arise, as well as reduced excretion of a large number of drugs and toxins [3, 9]. Multiple definitions of AKI have been proposed. Most recently, the Kidney Disease Improving Global Outcomes (KDIGO) workgroup proposed criteria for a single definition of AKI to be used in research and clinical practice which incorporates multiple studies [3]. The severity of AKI is graded based upon either changes in solute excretion (as measured by increases in serum creatinine) or by the duration and severity of oliguria. The initiation of renal replacement therapy (RRT) such as hemodialysis (HD) for a renal failure-related indication is also defined as AKI (Table 1).

Among hospitalized adults worldwide, the incidence of AKI is approximately 21.6% [15]. Drug toxicity accounts for a very large number of cases of AKI; in the largest meta-analysis performed to date, medications and radiocontrast media account for a combined 27% of the principle cause of AKI. The overall mortality of hospitalized patients was 19%; patients with higher degrees of AKI, unsurprisingly, had mortality rates which were higher yet [15]. The incidence

Table 1 KDIGO AKI staging

Stage	Serum creatinine	Urine output
1	1.5–1.9 times baseline or ≥ 0.3 mg/dl increase	<0.5 mL/kg/h for 6–12 h
2	2.0–2.9 times baseline	<0.5 mL/kg/h for ≥ 12 h
3	≥ 3.0 times baseline or increase in serum creatinine to ≥ 4.0 mg/dl or initiation of renal replacement therapy or in patients <18 years, decrease in eGFR to <35 mL/min per 1.73 m ²	<0.3 mL/kg/h for ≥ 24 h or anuria for ≥ 12 h

eGFR estimated glomerular filtration rate

of AKI is increasing among hospitalized patients in the United States, as is the incidence of AKI requiring renal replacement therapy [15, 16].

Traditionally, AKI is classified into three overarching subgroups based on underlying pathophysiology. *Prerenal failure* or *prerenal azotemia* describes AKI from reduced renal perfusion or any cause. *Intrinsic renal failure* encompasses a large group of disorders of renal parenchyma causing AKI; the most common cause of intrinsic renal failure is acute tubular necrosis (ATN) [9]. *Postrenal failure* refers to AKI from obstructive uropathy at any point along the urinary tract from the renal calyces to the outlet of the urethra. While prerenal azotemia accounts for the majority of all-cause AKI, the majority of AKI in critically ill patients is due to intrinsic renal failure [2, 3]. Postrenal failure generally accounts for less than 5% of significant AKI [2, 3]. While each cause of AKI is discussed separately, it should be noted that renal failure often occurs in the context of “multiple hits” that each cause worsening of kidney function, particularly where ischemic ATN is concerned.

Prerenal Acute Kidney Injury

Prerenal failure is a condition which arises due to hypoperfusion of the kidneys and is the most common type of AKI [17]. While hypovolemia is the most frequent cause of prerenal AKI, any condition that lowers renal blood flow may result

in a prerenal state: heart failure, cardiogenic shock, cirrhosis, and others [9]. Prolonged or severe prerenal azotemia may lead to renal hypoperfusion and produce ATN [9]. Any cause of hypovolemia may lead to prerenal azotemia, encompassing not only inadequate volume intake and fluid losses but processes resulting in vascular leakage (“third spacing”) such as sepsis [9]. Poisonings that result in volume depletion – such as those causing diarrhea, increased insensible losses, reduced enteral intake due to altered mental status, bleeding, and a host of causes – may cause prerenal azotemia. In these cases, prerenal failure due to hypovolemia may be distinguished from other causes of renal failure by administering intravenous fluids and observing the response.

A number of drugs may affect renal blood flow. Nonsteroidal anti-inflammatory drugs (NSAIDs) such as ibuprofen inhibit prostaglandin synthesis, resulting in reduced vasodilation of the afferent and efferent arterioles. The subsequent disruption to renal autoregulation decreases RBF, which causes prerenal azotemia [18]. Settings which lead to hypovolemia in patients taking NSAIDs further worsen renal blood flow and further increase risk for AKI [9]. The use of NSAIDs leads to a 50–100% increase in the risk of AKI compared to nonusers; this risk has not been demonstrated to be greater for one type of NSAID compared to others [19]. Acute NSAID overdose usually causes prerenal failure which is readily reversible with intravenous fluids, although intrinsic AKI requiring RRT has been described [20]. Multiple other classes of drugs may cause renal vasoconstriction, such as angiotensin-converting enzyme inhibitors, iodinated radiocontrast, and calcineurin inhibitors such as tacrolimus [9].

Poisoning causing cardiogenic shock may result in acute cardiorenal syndrome, a condition where heart failure leads to reduced renal perfusion [21]. While blood volume may be normal (and is often elevated), decreased cardiac output results in reduced renal perfusion, leading to dysfunctional autoregulation of GFR [21, 22]. Poisonings that result in acute heart failure and/or cardiogenic shock, such as cardiac sodium channel blocker, calcium channel blocker, and beta-

Table 2 Major causes of prerenal acute kidney injury

Intravascular volume depletion
Burns and skin breakdown (e.g., Stevens-Johnson syndrome)

Fever and hyperthermia
GI losses (diarrhea, vomiting)
Hemorrhage
Reduced enteral fluid intake
Vascular leak (“third spacing”)
Cardiorenal syndrome
Cardiogenic shock
Pulmonary hypertension
Cardiac tamponade
Decreased renal perfusion with normal or high cardiac output
Cirrhosis and hepatorenal syndrome
Sepsis
Vasodilator poisoning
Renal vasoconstriction
Angiotensin-converting enzyme inhibitors/angiotensin II inhibitors
Antimicrobials (amphotericin B, foscarnet, others)
NSAIDs
Cyclosporine and tacrolimus
Radiocontrast agents

blocker toxicity among many others, may result in AKI due to cardiorenal syndrome (Table 2).

Intrinsic Acute Kidney Injury

Intrinsic AKI refers to a broad swath of disease processes which cause renal failure due to damage to renal architecture. This class encompasses diseases affecting the renal tubules, such as acute tubular necrosis or intratubular crystalluria; the renal interstitium, such as acute interstitial nephritis; the renal microvasculature, such as thrombotic microangiopathy or vasculitis; and/or the glomeruli, such as glomerulonephritis. Table 3 lists many toxic causes of various forms of intrinsic AKI.

Acute tubular necrosis (ATN) and tubular injury is generally thought to account for the majority of cases of intrinsic AKI [3, 9, 15]. The renal tubules are vulnerable to injury from hypoperfusion; if the tubules, and particularly the proximal tubule, have reduced blood flow or

hypoxic injury to a point where oxygen delivery to tissues is impaired and ischemia occurs, tubular injury and necrosis may result [9, 23]. In addition, as the renal tubules are involved in reabsorption and secretion of many organic compounds, toxins and drugs frequently reach very high concentrations relative to other tissues and may exert an adverse effect on renal tissue. The S3 (most distal) segment of the proximal tubule has limited ability to carry out anaerobic glycolysis and is at higher risk for ischemic injury than other parts of the nephron [23]. Because of the role of the proximal tubule in carrying out the majority of drug reabsorption through endocytosis, most ATN due directly to tubular toxicity occurs in the proximal tubule, particularly affecting the S1 and S2 (more proximal) segments of the proximal tubule [24]. Pathologically, tubular injury is visible on kidney biopsy samples [24].

Acute tubular injury and necrosis from ischemic injury may result from any cause of reduced renal perfusion; in the poisoned patient, this usually results from shock or hypoxic injury. Severe prerenal azotemia from hypovolemia, cardiorenal syndrome, or medications affecting renal blood flow may also progress to ATN [23]. In patients

with preexisting chronic kidney disease, renal autoregulation is impaired; this may lead to earlier development of ATN and reduced likelihood of renal recovery [9].

A host of nephrotoxins may cause damage to the renal tubules in both therapeutic use and poisoning. Many antimicrobial agents, such as aminoglycosides, amphotericin B, and vancomycin, can be nephrotoxic in short-term use. Natural products such as aristolochic acid (found in Chinese traditional medicine) may cause both AKI as well as chronic kidney damage with repeated use [25]. Aristolochic acid may also cause kidney tumor formation; an outbreak of grain contaminated with *Aristolochia* species leads to endemic chronic kidney disease and kidney tumors in Eastern Europe termed Balkan chronic nephropathy [26]. Toxins causing oxidative renal injury, such as diquat, paraquat, and orellanine, may lead to tubular damage [27, 28]. Refer to Table 3 for a partial list of nephrotoxic compounds that may produce ATN.

Most cases of acute interstitial nephritis (AIN) are thought to be caused by idiosyncratic allergic reactions to various drugs [29]. Kidney biopsy findings in patients with AIN reveal an inflammatory infiltrate within the renal interstitium most often comprised of eosinophils (although neutrophilic or other infiltrates may occur). Often, other phenomena suggesting systemic allergic or inflammatory reactions may be present, such as fever or rash. Eosinophils are also found in the urine, although this is often not a sensitive finding due to their fragility [24, 29]. Common drugs implicated in the cause of AIN include antibiotics, proton pump inhibitors, and NSAIDs [30]. Medications that may cause other systemic allergic reactions, such as vancomycin, allopurinol, or phenytoin, may produce AIN as a manifestation of systemic disease [30, 31]. AIN may also result from autoimmune disease such as sarcoidosis [24]. Recently, synthetic cannabinoids have been implicated as a cause of AIN during outbreaks of synthetic cannabinoid-induced AKI; ATN was also commonly found [32]. It is not clear if this is allergic in nature or represents a different mechanism of interstitial inflammation such as apoptosis [33].

Glomerulonephritis and vasculitis are rarely caused primarily by poisoning, although cases do exist. Typically, these diseases are autoimmune in nature; this may still be the underlying pathophysiology in cases induced by poisoning, although no evidence exists to confirm or deny this. More likely, a variety of types of pathophysiology are present; however, clear models to describe the cause of drug-induced variants of most of these rare conditions do not exist, and pathophysiologic mechanisms remain speculative. Methamphetamines have been associated with C3 glomerulopathy, a form of membranoproliferative glomerulonephritis [34]. Necrotizing vasculitis (anti-neutrophil cytoplasmic antibody negative) has been associated with methylenedioxymethamphetamine [35, 36]. Levamisole, an antihelminthic drug which is commonly found as a contaminant in cocaine, has been associated with small vessel vasculitis similar to granulomatosis with polyangiitis; this may cause rapidly progressive glomerulonephritis with crescents [37]. Heroin has been associated with collapsing focal segmental glomerulosclerosis [38].

Thrombotic microangiopathies (TMAs) refer to a wide category of conditions which result in microangiopathic hemolytic anemia, the presence of microthrombi in a systemic or local distribution, and a constellation of clinical findings as a result. The kidneys are frequently involved in TMAs; the nature of the extensive network of renal arterioles and capillaries is often a nidus for clot formation [39]. Thrombotic thrombocytopenic purpura (TTP) is a prototypical TMA; it may produce multiple, often very severe, manifestations such as severe thrombocytopenia, renal failure, anemia, stroke, myocardial infarction, and seizures [39]. Hemolytic-uremic syndrome (HUS), in contrast, is a predominantly renal-limited TMA which usually causes significant AKI but has extremely varied systemic symptoms [39]. While most TMAs were previously categorized under the umbrella of either TTP or HUS, a more nuanced pathophysiologic approach is often taken nowadays, with drug-induced TMA simply being referred to as such.

Multiple drugs and agents have been associated with TMA; a partial list is found in Table 3.

Notably, while many drugs have been associated with TMA, only about one-quarter have clear evidence to establish a causal relationship [40]. In a series of cases of note, intravenous use of extended-release preparations of oxymorphone (Oxymorphone ER) was associated with a rash of cases of TTP-like thrombotic microangiopathy [41, 42]. The extended-release preparation of oxymorphone involved was formulated with a tamper-resistant matrix which forms a gel-like substance when heated; it is unclear whether the nature of TMA in this case is due to the drug itself or the tamper-resistant compounds.

Rhabdomyolysis leads to development of AKI through high concentrations of heme breakdown products and myoglobin in renal tubules; these lead to intratubular cast formation, direct tubulotoxicity, and renal vasoconstriction [43]. Many poisonings may produce rhabdomyolysis from direct muscle injury and/or systemic hypoperfusion; a partial list is mentioned in Table 3. Sympathomimetic toxins are particularly likely to cause drug-induced rhabdomyolysis; among these agents, synthetic cathinones may lead to greater degrees of rhabdomyolysis than cocaine and amphetamines [44]. The risk of AKI is directly correlated with the elevation in creatinine kinase – patients with creatine kinase elevations above 20–25,000 units/L have a risk for AKI which is an order of magnitude greater than lower elevations [45, 46]. While much less common than rhabdomyolysis, significant hemoglobinuria may also produce heme pigment nephropathy; toxins causing massive hemolysis, such as benzene or arsine gas, and *Loxosceles* venom may produce AKI in this manner [24, 47].

Crystalluria may be caused by a number of drugs in acute poisoning or chronic use; however, not all are equally likely to cause AKI. Drugs that form sharp, needlelike crystals such as acyclovir or indinavir are more likely to cause AKI than others [48]. Mechanisms by which crystalluria may induce AKI through blockage of renal tubules, damage to renal tubular epithelium, or both [49]. Not all drugs that cause crystalluria are likely to induce AKI; e.g., primidone may cause massive crystalluria but is less likely to cause AKI, and beta-lactams may cause microscopic crystalluria

Table 4 Major drugs and toxins known to cause crystalluria-induced AKI

Methotrexate
Primidone
Sulfamethoxazole and other sulfa antibiotics
Triamterene

but have not been reported to cause AKI through this mechanism [24, 49].

Factors which increase the risk of crystalluria-induced AKI largely result in the production of low urine volumes; this leads to a higher drug concentration to form inside renal tubules, increasing the likelihood of crystalluria. Examples of risk factors include hypovolemia, preexisting AKI or CKD, high doses of drugs, and concurrent NSAID use. Higher doses of drugs are an important risk factor for AKI; in high-dose sulfamethoxazole use (e.g., as used in treatment of *Pneumocystis*, *Stenotrophomonas*, and other organisms), development of AKI is more likely to occur in patients with preexisting CKD [50]. Depending on the nature of the drug involved (i.e., whether it is more likely to form crystals in acidic or basic urine), either high pH or low pH may also be a risk factor [49]. Medications notorious for causing AKI through crystalluria include acyclovir, methotrexate, sulfamethoxazole, and others; a partial list is given in Table 4.

Analgesic nephropathy is mentioned mostly for historical interest, as the incidence of this condition has dropped dramatically since its recognition [51]. Rather than encompassing all analgesic-induced AKI (e.g., NSAIDs), classic analgesic nephropathy refers to a slowly progressive form of chronic kidney disease that results from chronic high-dose use of multiple over-the-counter analgesic agents including at least two antipyretic agents, one of which was usually phenacetin, plus caffeine. More patients were identified per capita in Australia than in any other country, likely related to local analgesic

availability and habits – in 1990, analgesic nephropathy accounted for nearly 10% of end-stage renal disease in Australia. The disease results in chronic interstitial nephritis, renal papillary necrosis, and characteristic “lumpy” kidney contours on renal imaging [51].

Osmotic nephrosis is an uncommon kidney injury pattern seen in response to high-osmolality medications such as sucrose-containing intravenous immunoglobulin, hydroxyethyl starch, and iodinated contrast. The pathophysiology is thought to be related to excess solute accumulation by the proximal tubules in response to a high osmotic load, leading to massive vacuolization and tubular injury [52]. Another uncommon cause of AKI, phosphate nephropathy, was first identified in the early 2000s. A series of patients who took oral phosphate salts as bowel preparation for endoscopy presented with AKI; kidney biopsy findings revealed extensive intraluminal and tubular calcium phosphate deposition, suggesting that a transient extremely high serum phosphorus level led to massive phosphate excretion with crystal formation. Many patients with phosphate nephropathy do not recover kidney function after the injury; anecdotally, phosphate crystals may be present years later on kidney biopsies [53].

Postrenal Failure

Postrenal failure, or AKI related to obstruction at any point along the urinary tract from the renal papillae to the urethral outlet, accounts for far fewer cases of AKI than prerenal or intrinsic renal causes [9, 24]. In poisoning, postrenal failure is usually related to urinary obstruction through bladder wall contraction; agents which commonly cause this include opioids, anticholinergic medications, and antidepressants. While postrenal failure is reversible in the acute setting, prolonged obstruction may be associated with surprisingly few symptoms, and irreversible renal failure can develop when obstruction is present for a long duration of time [54].

More recently, ketamine and related analogues (e.g., methoxetamine) have been associated with

lower tract urinary dysfunction. A series of 59 patients in Hong Kong who used ketamine illicitly were found to have moderate to severe symptoms of urinary urgency, dysuria, and/or hematuria. On urodynamic studies, detrusor overactivity and decreased bladder compliance were common [55]. Similar findings have been noted in surveys of ketamine abusers [56]. Animal studies have produced evidence of postrenal failure and kidney damage in mice using ketamine; despite a perception that methoxetamine is more “bladder-friendly,” murine studies found evidence of bladder and renal toxicity with chronic methoxetamine administration [57, 58].

Diagnostic Evaluation of Acute Kidney Injury

The determination that AKI is present is a clinical diagnosis; while staging guidelines may be of help, at present, biomarkers of kidney injury which are more rapidly able to identify AKI are not in widespread clinical usage, although they may be helpful in the future [8]. Close attention to history and physical examination, urinary examination, laboratory testing, and renal imaging forms the cornerstone of evaluation of the AKI patient. In less common situations, a kidney biopsy may be of utility as well.

History taking in the patient with AKI and suspected poisoning should focus on potential ingestions as well as known exposures. In the hospitalized patient with AKI, drugs and medications are a common cause of renal failure [3, 15–17]. Examination should give special attention to evaluation of volume status, any findings to suggest systemic inflammatory disorders (vasculitic-appearing rash, livedo reticularis, etc.), and the presence of identifiable toxidromes (e.g., sympathomimetic toxidrome). The bladder should be palpated, and any prolonged period of anuria should prompt urinary catheterization to exclude lower urinary tract obstruction [3, 9].

Urinary analysis – both by chemical means (i.e., urine dipstick, laboratory parameters) and by visual inspection by the clinician – still occupies a core role in the evaluation of the patient

Table 5 Common urinary diagnostic indices in prerenal versus intrinsic renal failure

Parameter	Renal failure	
	<i>Prerenal</i>	<i>Intrinsic</i>
Urinalysis	Hyaline or no casts	Abnormal, cellular, or granular casts
Specific gravity	>1.020	Around 1.010
Urine osmolality (mOsm/kg)	>500	<350
Urine sodium (mmol/L)	<20	>20
FE sodium, %	<1	>2
FE urea, %	<35	>35
BUN:creatinine ratio	>20:1	<20:1

BUN blood urea nitrogen, *FE* fractional excretion

with AKI. Chemical and visual analysis probably plays the most significant role in distinguishing between prerenal failure (bland urine) and intrinsic renal failure (presence of abnormal findings); Table 5 summarizes the most commonly evaluated urinary diagnostic indices. When distinguishing between acute tubular necrosis and prerenal azotemia, the presence of “muddy-brown” granular casts is highly suggestive of ATN, although the absence of such casts is not particularly specific [24]. Microscopic evaluation of urine also serves to allow the astute clinician to find uncommon but very helpful specific urinary features, such as white blood cell casts (suggestive of acute interstitial nephritis), red blood cell casts (suggestive of glomerulonephritis), or crystalluria [3, 9].

It should be noted that urinary analysis is not perfect by any means, and a number of pitfalls exist for the clinician who relies too heavily upon it to diagnose AKI. The most important factor to remember when evaluating fractional excretion of sodium and other solutes is that this is only validated in the oliguric patient; in patients who are non-oliguria, these parameters are not very specific. Moreover, patients with underlying heart failure or cirrhosis will often have prerenal-appearing indices even in the setting of ATN. Urine which is allowed to sit for a prolonged period of time may have findings such as casts or eosinophils degrade; ideally, urine samples

should be collected from the freshest sample available (i.e., the urine furthest up in the urinary catheter, not the urine in the collecting bag!).

Ultrasound is the initial imaging modality of choice to evaluate AKI; not only is ultrasound able to visualize the kidneys and bladder well, it is noninvasive and can be obtained rapidly in most situations. While the chief utility of ultrasound in AKI is excluding obstructive uropathy as a cause, with a sensitivity of over 90%, it often is able to identify the presence of significant CKD as well through characterization of renal parenchyma. In some settings, computed tomography or other imaging modalities may be useful to identify the site of ureteral obstruction [9].

In certain situations, obtaining a kidney biopsy may be of utility in distinguishing certain types of AKI. Most clinical scenarios in which a biopsy may be considered are those where potential treatment changes are thought to justify the risk of performing the procedure. In a group comprised of largely outpatients, kidney biopsy carried 0.9% of a risk for bleeding, and 0.6% of patients needed angiographic intervention; this risk would be expected to be higher for biopsies in AKI [59]. Thus, in scenarios where a biopsy is unlikely to yield additional information – e.g., when AKI is likely due to ATN from shock or hypoxic injury – biopsy is largely avoided. Similarly, kidney biopsy is rarely performed when patients have thrombocytopenia, as this may increase bleeding risk over tenfold from average [60, 61]. When a patient’s presentation is suggestive of glomerular disease (proteinuria, hematuria) or AKI due to an unknown cause without clear reason to consider ATN, kidney biopsy may be worth considering.

Complications of AKI

In the setting of AKI, inability to excrete fluid and electrolytes and maintain acid–base balance may lead to volume overload, dangerous electrolyte derangements such as hyperkalemia and severe acidemia. Complications of isolated AKI arise slowly, over the course of days; however, as AKI often occurs in the context of multiorgan failure, loss of kidney function may exacerbate

electrolyte, acid–base, and volume disorders that arise from poisoning or the treatment of the poisoned patient.

The most dangerous electrolyte abnormality that may arise in AKI is usually hyperkalemia. Severely elevated potassium levels may lead to decreased inotropy and chronotropy, followed by fatal arrhythmias [62]. Hyperkalemia may be more likely to occur in patients who have AKI with concomitant processes that raise potassium levels, such as rhabdomyolysis or Na–K ATPase blockade. Mineral acidosis – aka non-anion gap acidosis – leads to hyperkalemia through intracellular buffering of acid through hydrogen–potassium antiports on red blood cells and various tissues [62]. It should be noted that this process does not occur to a great extent in lactic acidosis; lactic acid crosses cell membranes directly, decreasing the activity of the hydrogen–potassium antiport [63].

Other electrolyte disorders that may arise secondary to AKI include hyponatremia, hyperphosphatemia, and hypocalcemia; unlike hyperkalemia, these rarely produce life-threatening effects in the context of AKI [9, 62].

When kidney failure occurs, normal acid excretion mechanisms are not able to excrete the amount of acid generated each day, and non-gap acidosis (from lack of acid excretion) as well as an anion gap acidosis (from uremic toxins) develop over time. In poisoning with multiorgan failure causing lactic acidosis or in poisonings with other causes of acidosis (e.g., ethylene glycol ingestion), AKI may compound acidemia by removing normal mechanisms of toxin removal. If AKI occurs over a prolonged period of time, other complications usually seen in CKD may develop to an extent, such as anemia [3, 9].

Uremia – literally “urine in the blood” – is a constellation of symptoms and clinical effects that occur in the context of inability to excrete a variety of metabolites termed “uremic toxins.” These toxins include small molecules as well as small- and medium-sized proteins. Early symptoms of uremia include poor appetite, abnormal taste in the mouth, fatigue, and difficulty concentrating. Severe symptoms, usually arising after a prolonged period of reduced renal function,

include encephalopathy, seizures, abnormal bleeding, neuropathy, and pericarditis [9]. Bleeding from uremia is related to platelet dysfunction and reduced clotting factor activity and may not respond well to administration of clotting factors [64]. Pericarditis is typically hemorrhagic and may lead to acute or chronic cardiac tamponade. Unlike hyperkalemia and acidemia, which often may be mitigated before hemodialysis can occur, severe manifestations of uremia often respond less well to medical therapy other than urgent hemodialysis [3, 9].

A number of poisonings are treated by rapid intravenous fluid administration; in these cases, AKI may lead to volume overload, complicating patient management. This may lead to particularly difficult problems in the setting of toxin-induced cardiogenic shock, where development of pulmonary edema may be accelerated due to decreased inotropy. Volume overload in the setting of AKI usually necessitates dialysis; as some patients may respond to diuretic therapy, this is a reasonable intervention to attempt as long as hemodialysis is not delayed when clinically necessary [3].

When the kidneys are a major route through which a toxin or drug is excreted, AKI may worsen toxicity through greater periods of high toxin concentration; prominent examples of this include methotrexate, salicylate, and lithium poisoning, among others [65–67]. In cases of crystalluria-induced AKI, this may lead to a vicious circle where AKI leads to prolonged drug retention in renal tubules, leading to increased drug precipitation and worsened AKI [48].

Management of Acute Kidney Injury

Supportive care is the cornerstone of management of AKI. In general, the goals of AKI management are to identify and reverse any underlying cause (s), mitigate further deterioration of renal function, treat complications such as electrolyte disorders and volume overload (including consideration of renal replacement therapy), and provide general supportive care to the patient [3].

Hypovolemic prerenal failure should be treated with adequate volume resuscitation. There is little benefit to colloid over crystalloid solutions in most clinical scenarios, although intravenous albumin has a clear role in managing AKI in patients with substantial liver failure [3]. Discontinuing or minimizing drugs likely to cause renal vasoconstriction is recommended, although not always feasible (e.g., discontinuation of tacrolimus in a new heart transplant patient). Prerenal failure due to poisonings which affect renal hemodynamics, such as NSAIDs, usually responds to intravenous fluid resuscitation alone. In settings where renal hemodynamics were profoundly affected and ischemic ATN is present, however, care should be taken to avoid excess volume resuscitation, as this may lead to poorer outcomes [3, 68]. In overdose settings where prerenal failure is due to cardiorenal syndrome, hemodynamics should be optimized; this may require the use of inotropes and/or invasive monitoring [21, 22].

When ischemic or toxic ATN is present, the kidney will have reduced metabolic capacity to deal with further injury, and care should focus upon avoiding further events which could compound AKI. Whenever possible, nephrotoxic drugs should be withheld or minimized. Even if ischemic ATN was not the cause of renal failure, in the setting of AKI, the kidney's ability to carry out normal autoregulation is compromised; adequate mean arterial pressures (usually 65 mmHg, sometimes higher) should be maintained as necessary [3, 9, 24].

Development of AKI from pigment nephropathy in rhabdomyolysis is best avoided through administration of aggressive isotonic fluids to increase urinary output and thus heme breakdown product formation [9]. While risk-scoring systems have been developed to estimate the risk of need for dialysis, there is little evidence to suggest that other therapies besides intravenous fluids are of utility. A single review of rhabdomyolysis in patients with trauma ICU admissions found a statistically nonsignificant ($p < 0.09$) trend toward benefit in administration of sodium bicarbonate and mannitol in patients with creatine kinase levels greater than 30,000 units/L; no

randomized trials for bicarbonate versus isotonic saline exist [45].

Drug-induced vasculitic disease, glomerulonephritis, and thrombotic microangiopathies are often treated in much the same way as their counterparts not caused by drugs. Few studies exist to guide the clinician with a rare case of drug or toxin-induced vasculitis; in addition to discontinuing the suspected agent, immunosuppression is often worth considering as the pathophysiology of such diseases is not well understood. While plasma exchange is a consideration for drug-induced thrombotic microangiopathies, most of the available data suggests against the use of this modality due to lack of evidence of efficacy [69].

The major goals of treatment of crystal-induced AKI are to flush out any existing crystals and reduce the likelihood of further crystal formation. Often, AKI from crystalluria may be avoided or mitigated by providing high urinary flow through extensive intravenous fluid administration along with drug usage. After AKI has occurred, this approach may still be of utility, although careful monitoring to avoid volume overload is often necessary. Depending on the drug or toxin (e.g., methotrexate), urinary alkalinization may be of utility [48].

Acute interstitial nephritis is primarily treated by removing the drug thought to be causative. There is evidence both for and against the use of corticosteroids to decrease the inflammatory process, with mixed results from studies; the best available data seems to suggest that if steroids are initiated, they should be initiated as soon as possible and tapered over at least 2 weeks (if not 4–6 weeks) [9, 70, 71].

Postrenal failure is treated by relief of the obstruction; depending on the nature and location of the urinary obstruction, this may involve the use of a urinary catheter, suprapubic catheter, ureteral stent, and/or nephrostomy tube [3, 9, 24]. For short-lived bladder obstructions as caused by anticholinergic medications or opioids, a temporary urinary catheter is usually sufficient.

Complications of AKI, such as volume overload and electrolyte imbalances, may be dealt with either medically or via the use of renal

replacement therapy. Diuretic therapy has been demonstrated to not greatly affect the outcome of AKI, although a patient's response to diuretic therapy may predict whether RRT will ultimately be needed [72]. Indications for renal replacement therapy are abbreviated by the acronym "AEIOU" – acidosis, electrolyte imbalance, intoxication, volume overload, and uremia refractory to medical management. Methods of renal replacement therapy available for the patient with AKI include hemodialysis (HD), continuous renal replacement therapy (CRRT), and in some locations (largely outside of the United States) peritoneal dialysis (PD). All three therapies act through the processes of diffusion (movement of solutes from high to low concentration), convection (passive "solvent drag" of solutes along with movement of water), and ultrafiltration (movement of fluid driven by a pressure gradient) to remove toxins, restore electrolyte balance, and remove excessive fluid volume. Acute peritoneal dialysis is generally not chosen for management of AKI except in special circumstances (e.g., developing countries where hemodialysis is unavailable, infants and children too small to undergo CRRT) [3, 9].

No clinical trial has ever evaluated the utility of acute hemodialysis for life-threatening complications of AKI; however, hemodialysis is widely used for patients who have or are reasonably expected to develop if untreated with dialysis, severe complications of AKI. While hemodialysis is commonly employed for noncritically ill patients with AKI, either HD or CRRT may be employed for patients with shock or other critical illness [3].

The literature concerning choice of HD versus CRRT in critically ill patients with AKI does not show benefit for one therapy versus another; however, this literature is generally derived from treatment of patients with postsurgical or septic shock rather than acutely poisoned patients. In many settings where both therapies are available, CRRT is commonly chosen for management of patients with shock due to the ability to perform slow volume removal, which is often better tolerated by patients due to reduced hypotension [3]. Similarly, patients treated with CRRT for AKI in the setting of shock generally have a reduced need for vasopressors [3, 9, 73].

For patients without shock due to poisoning who do not require extracorporeal toxin removal, CRRT and SLED (slow low-efficiency dialysis, which is performed using an HD machine) are both appropriate therapies [74]. When patients have AKI without shock, hemodialysis and CRRT are appropriate therapies; in this setting, hemodialysis is commonly performed [3].

In settings where extracorporeal removal of toxins is needed in addition to renal replacement therapy, strong consideration of HD should be given (even in the setting of shock) due to its greater ability to remove toxins quickly. At maximal settings, the ability of HD to remove toxins is several times greater than CRRT for most toxins [66, 67]. Similarly, renal replacement therapy should be instituted in a timely manner when appropriate to limit the risk of patient decompensation [66]. Often, from time of initial contact of the nephrologist to the start of hemodialysis takes several hours even in emergent situations; in settings where this speed can be reduced due to systems in place that allow for rapid catheter placement and immediate preparation of the dialysis machine, it is very likely that this process will still take over an hour. Thus, early consultation of a nephrologist in situations where extracorporeal therapy may be required for supportive care and/or drug removal is of paramount importance.

The central nervous system (CNS), with its large lipid content and extensive blood supply, is often the target organ of drugs or toxins (toxicants). Signs resulting from chemical effects on the CNS frequently include mental status changes often progressing to coma. Coma may be due to direct toxic effects, metabolic abnormalities, or anoxia. A review of the final diagnosis of 500 patients hospitalized with “coma of unknown etiology” found that 149 (30%) were due to the adverse effects of drugs, with metabolic disorders accounting for 35% of cases [1].

Pathophysiology

Alterations in consciousness can be classified into several categories. *Lethargy* (or somnolence) denotes an inability to maintain the wakeful state without external stimulation, whereas *stupor* is defined as arousability only in response to a vigorous or noxious stimulus. Arousal usually does not outlast the stimulus application. *Obtundation* implies a patient who is aroused by loud speech or gentle shaking but appears to be confused upon arousal. *Delirium*, or acute cortical–subcortical neuronal encephalopathy, is a fluctuating condition characterized by confusion, irritability, and disorientation that develop over a short period. The mental status end point of impaired consciousness is *coma* (unresponsiveness that is not arousable by any stimulus). Seizures may occur at any point. Substance intoxication and withdrawal

are common causes of delirium and can cause seizures or coma. Mental status changes due to drugs or toxins usually are characterized by three tenets: (1) a strong dose–response relationship, (2) occurrence either at the time of exposure or after a short latent period, and (3) neurological improvement after cessation of exposure, unless a secondary process, such as the effect of prolonged hypoxia or seizures, supervenes [2].

Disturbances in consciousness leading to coma directly due to drugs or toxins usually are due to the suppression of activity in the neurons located in the reticular activating system of the upper brainstem and throughout the cerebral cortex. The reticular activating system is interspersed through paramedian regions of the rostral pontine and midbrain tegmentum, in the thalamus and the midbrain [3]. Although damage to the dominant (language-producing) cerebral hemisphere can produce temporary coma, prolonged coma due to a toxic insult implies bilateral (global) hemispheric or midbrain (through the reticular activating system) involvement. Alteration in consciousness may result from direct effect of the toxicant on the neuronal membranes of the reticular activating system or cerebral cortex (e.g., ethanol and general anesthetics).

Drugs or toxins (e.g., organophosphate agents, nicotine, or barbiturates) may also interact with neuroreceptors and neurotransmitters [3]. Examples include the enhancement of γ -aminobutyric acid (GABA) inhibitory influences on presynaptic and postsynaptic receptors, resulting in the opening of neuronal chloride channels. The resulting influx of chloride ions increases the negative resting potential, causing hyperpolarization, which stabilizes the nerve membrane and reduces neuronal firing rate [4–6]. Other drugs (e.g., benzodiazepines) increase the intracellular flux of chloride ions by enhancing GABA binding to other (GABA_A receptors) neuroreceptor sites and by unmasking high-affinity GABA receptors [6]. Table 1 and Fig. 1 present neurotoxic agents and their targets for disruption of neurosynaptic transmission. Metabolic neuronal disturbances (due to factors such as concomitant hypoxia, hyperkalemia, hypokalemia, acidosis, or vitamin deficiencies) are an additional mechanism for

Table 1 Cellular targets and potentially neurotoxic agents

Acetylcholine	Aminopyridines, Black widow spider venom, botulinum toxin, crotoalid and elapid venom
Acetylcholinesterase	Physostigmine, edrophonium, carbamate insecticides, organophosphates
Adenosine receptors	Adenosine, caffeine, carbamazepine, TCAs, indomethacin
α -Adrenergic receptors	Dobutamine, phenylephrine, clozapine, ergot alkaloids, terazosin, olanzapine, clonidine, guanfacine, dexmedetomidine
β -Adrenergic receptors	Epinephrine, norepinephrine, albuterol, ritodrine, beta-blockers

impaired consciousness. Hypoglycemia (serum glucose <40 mg/dL [2.2 mmol/L]) can result in cerebral cortex or brainstem dysfunction or both, occasionally also causing focal neurologic deficits.

An additional mechanism for coma production involves cerebral nitric oxide production through the enzyme nitric oxide synthase, which is involved in *N*-methyl-D-aspartate receptor activation. Neurodegeneration attributable to nitric oxide production is due to a peroxynitrite-induced oxidant stress, leading to endothelial damage in cerebral blood vessels, reversal of platelet aggregation, and cerebellar synaptic depression. This

Fig. 1 Schematic representation of a synapse showing the principal structures and sites of drug action. This synapse is a hybrid for the purpose of visualization; as outlined in the text, a neuron is typically highly specialized for a specific neurotransmitter system. *GABA* γ -aminobutyric acid, *5-HT* 5-hydroxytryptamine, *MAO* monoamine oxidase, *Ntx* neurotransmitter (From Burkhart and Akhtar [7])

mechanism is probably involved in the mediation of carbon monoxide, glutamate, sodium nitrite, and paraquat toxicity. Other toxins involved in *N*-methyl-D-aspartate receptor activity include domoic acid and acute ethanol withdrawal.

Delirium can be caused by virtually any drug, but it is especially noted with anticholinergic drugs (Table 2). It can be considered as a disorder of neurotransmission in the cortical and subcortical regions of the brain involving acetylcholine, dopamine, GABA, and serotonin [8–10].

Clinical Characteristics

Delirium may be hypoactive, with inattention and decreased activity, or hyperactive, characterized by agitation and combativeness. It is a disorder of attention and arousal and can be detected easily using the confusion assessment method. The *Diagnostic and Statistical Manual of Mental Disorders, Fifth Edition* [11], criteria specify three aspects of the clinical characteristics of delirium: (1) onset within hours or days, with fluctuation

during the course of the day and usually worse at night, (2) cognition change (disorientation, memory deficit, or language disturbance), and (3) disturbance of consciousness with a reduction of ability to focus, sustain, or shift attention. After recovery, the patient usually is amnesic about the delirium episode.

The general clinical characteristics of coma due to an acute toxic cause are an absence of meningeal irritation and a lack of focal neurologic signs (unless hypoglycemia is involved). Usually no discrete morphologic causative lesion can be detected on neuroimaging. In the absence of seizures, the patient often progresses to coma through varying stages of lethargy, confusion, and stupor with these stages often noted on reemergence from the comatose state. Deep tendon reflexes and oculocephalic and oculovestibular reactions are also usually preserved except in intoxications involving sedative-hypnotics and anticonvulsant agents. Agents causing prolonged coma (possibly lasting for >100 h) with intermittent periods of arousal are usually drugs that undergo enterohepatic or

enteroenteric recirculation of their active metabolites, resulting in cyclic coma (Table 3).

Ancillary clinical signs are essential in determination of the toxic etiology. An adequate ocular examination is crucial [12]. The salient feature of the ocular examination can be divided into three categories: pupillary size, pupillary reactivity, and assessment of the presence of nystagmus.

The pupillary size represents a constant balance between the autonomically innervated sphincter pupillae and the radially arranged dilator muscle of the iris. In toxic cases, the pupillary size is generally symmetrical, although 20% of normal individuals exhibit up to 0.5 mm of asymmetry [3]. Tables 4 and 5 list agents that may cause miosis (pupils <2 mm) and mydriasis (pupils >4 mm) [13]. Pupil size can be variable in drug toxicity, however, due to multiple conflicting neurotransmitter responses in critical illness, and also polydrug ingestion of drugs with competing pupillary activity is not a consistently reliable diagnostic finding [14].

The pupillary light reflex is usually spared in coma of toxic origin; however, there are some exceptions. High-dose barbiturate poisoning and opiates can result in fixed miosis, whereas anticholinergic agents can cause fixed mydriasis that may not be reversible with physostigmine. Other causes of midrange-to-large, fixed pupils include methanol toxicity, hypothermia, and hypoxia [3].

Drug-induced nystagmus (involuntary rhythmic eye movement) commonly results in “jerk nystagmus.” In jerk nystagmus, the eye movements alternate between the slow component of initial (or induced) movement and the fast corrective component (jerk) in the opposite direction. Common causes for horizontal nystagmus include alcohol, anticonvulsants, sedative–hypnotics, solvents, and quinine. Lithium may cause downbeat nystagmus [15]. Phencyclidine, dextromethorphan, phenytoin, and sedative–hypnotics may cause a combination of vertical, horizontal, and rotary nystagmus. Sedative–hypnotics may cause disconjugate gaze. Opsoclonus (rapid, conjugate eye oscillations worsened by voluntary movement) may be caused by intoxication with antidepressants, anticonvulsants, organophosphates, thallium, lithium, and haloperidol. Periodic gaze disturbances (“ping-pong” gaze) have been described with monoamine oxidase inhibitor intoxication [16]. Anoxic coma causing cortical dysfunction can result in a cyclic downward dipping motion of the eyes (ocular dipping) [17].

Several agents can cause intracranial hypertension (pseudotumor cerebri) (Table 6). While most cases are limited to single case reports (i.e., phenytoin, indomethacin, danazol), the vitamin A derivatives (including topical formulations) have been particularly associated as causes [18].

Posterior reversible encephalopathy syndrome (PRES) is a recently described entity that causes cortical visual loss, visual field defects, seizures, and mental status changes. Several conditions are associated with PRES, including hypertensive crisis, hepatic encephalopathy, and eclampsia; toxic responses to medications are described in Table 7 [18].

The nature of the respiratory response is a valuable clinical clue to ascertain a toxicologic cause in the patient with altered mental status. Slow, regular breathing (usually at a rate <12 breaths/min) indicates an opiate or sedative–hypnotic toxicity. These drugs inhibit the pontine and medullary respiratory centers, resulting in diminished responsiveness of these centers to increases in carbon dioxide tension [18, 19]. Alternatively, sympathomimetic agents directly stimulate these respiratory centers, resulting in tachypnea with increased tidal

volume [3]. Kussmaul respirations (rapid, regular respirations with large tidal volumes) are usually related to metabolic acidosis. Another typical respiratory pattern due to acute intoxication is Cheyne–Stokes respiration. This pattern is characterized by periods of hyperpnea that regularly alternate with a shorter period of apnea. This abnormal pattern is due to neuronal metabolic disturbances, which isolate the respiratory center in the brainstem from the cerebral cortex. Pulmonary complications, such as acute respiratory distress syndrome (e.g., caused by salicylates, opioids, cyclic antidepressants, sedative–hypnotics) and aspiration pneumonitis, are indirect consequences of toxin-induced coma. Aspiration pneumonitis occurs in approximately 10% of patients hospitalized after a drug overdose and more frequently when mental status is depressed [20].

Cranial nerve dysfunction may be observed in patients with toxin-induced impaired consciousness (Table 8). Examples include trichloroethylene causing trigeminal nerve sensory neuropathy and organophosphate exposure involving multiple cranial nerves. These cranial neuropathies are usually bilateral. Nonspecific neurologic signs, such as asterixis, fasciculation, and myoclonus, are associated with toxic delirium and are not caused by psychiatric conditions mimicking delirium (see Table 2) [21–23]. Motor response to noxious stimuli is symmetric and nonfocal. Anticholinergic medications are associated specifically with an increase in delirium incidence and severity in elderly patients [24]. This

increase is thought to be due to the frequency of anticholinergic drug prescribing in the elderly, age-related decrease in cholinergic neurotransmission, pharmacodynamic changes in cholinergic receptor sensitivity, and deficient drug metabolism and elimination [25]. Antibiotics reported to cause a toxic encephalopathy and/or toxic psychosis include the beta-lactams, cephalosporins (which can cause triphasic waves on the electroencephalogram), trimethoprim–sulfamethoxazole, quinolones, and linezolid [26].

Laboratory Studies

Diagnostic modalities used to determine the cause of altered mental status usually are focused on serum analysis rather than on acute neuroimaging studies. Any toxic cause of high anion gap metabolic acidosis requires investigation. The presence of a decreased anion gap suggests lithium or bromide exposure. The presence of an osmolar gap usually indicates ethanol, isopropanol, methanol, or ethylene glycol poisoning, diabetic ketoacidosis, sepsis, or alcoholic ketoacidosis. Pure respiratory acidosis is consistent with hypoventilation, a clue to possible intoxication with sedative–hypnotics or opioids. Although urinary immunoassay results may provide a clue to the cause of altered consciousness, they often yield misleading false-positive and false-negative results. Serum concentrations of specific drugs can be diagnostic and are more useful if available (Table 9). Tricyclic antidepressant intoxication can lead to electrocardiographic abnormalities, dysrhythmias, and seizures (described in chapter on tricyclic antidepressants). Patients with QRS interval prolongation greater than 0.1 s with QRS axis shifted to the right (as is the axis in the terminal 40 ms of the QRS interval) may be at risk for neurologic complications [27]. This is seen most easily as a terminal R wave in lead AVR. For this reason, a screening electrocardiogram often is used in the initial assessment of patients with coma or seizures. Hair testing for the presence of drugs provides only qualitative interpretation, is fraught with technical

difficulties, and offers no utility in the acute investigative causes of coma [28].

The electroencephalogram is useful in assessing cerebral cortical dysfunction and identifying seizure activity. Normal alpha with theta-delta (grade I) activity is compatible with a good prognosis, as is paradoxical monomorphic delta activity, whereas low-voltage delta activity (with alpha coma), alternating patterns, or isoelectric

tracing (grades IV or V) is indicative of a poor prognosis [29, 30]. Brainstem auditory evoked potentials correspond with brainstem dysfunction during coma and may be modified by anesthetics and barbiturates [31–35].

Treatment of Patients with Altered Mentation

Respiratory compromise is the primary life threat in most toxic exposures causing alterations of consciousness. Maintenance of airway patency and respiration must be prioritized. Endotracheal intubation may be required, particularly if the patient does not rapidly respond to reversal maneuvers (such as naloxone) [36]. A complete set of vital signs including temperature is mandatory. Supplemental oxygen should be administered if there is a suspicion of hypoxia or carbon

monoxide poisoning. Rapid determination of blood glucose should be performed [37]. If the patient is determined to be hypoglycemic, or if rapid measurement is unavailable, dextrose should be administered [38].

Gastrointestinal decontamination with activated charcoal is of possible benefit in some toxic ingestions, especially if given early after ingestion. Activated charcoal should be administered cautiously, if at all, in non-intubated patients who may have ingested an agent that may cause a decline in the level of consciousness. Multiple dosing of activated charcoal can enhance the elimination of the few drugs listed in Table 3 (except for clonazepam and olazepine). Whole-bowel irrigation with polyethylene glycol may be warranted in ingestions of drug packets or medications not found to bind to activated charcoal, such as lithium or iron tablets [39]. All of these techniques have possible morbidity, however, and none have been shown to alter outcome in poisoned patients. After initial stabilization measures and decontamination, most toxicities may be managed expectantly. If the agent is known, specific antidotal therapy may be indicated (Table 10). Use of a series of agents – a “coma cocktail” – is often employed as a diagnostic and therapeutic strategy in a patient with altered mental status of unknown etiology. Dextrose with thiamine, supplemental oxygen, and naloxone is used widely in this setting. Two other antidotal agents, flumazenil and physostigmine, at one time also were considered components of the coma cocktail. Because of concern over the safety of these agents, however, many authors have discouraged their indiscriminate use in comatose patients with an unknown ingestion [40–43]. Familiarity with these agents, including risks and benefits of their use, is essential.

Opioid Antagonists

Opioids produce alterations in consciousness via interaction with multiple opioid receptors (μ_1 , μ_2 , κ , and δ) located in the CNS. Stimulation of these receptors results in analgesia, euphoria, CNS and respiratory depression, and miosis. Although naloxone and nalmefene are structural analogues of morphine, they possess no agonist activity of their own. When administered, these agents antagonize the effect of opioids by competing for opioid receptor sites. Naloxone is the opioid antagonist

	Nitroprusside

most frequently used in the prehospital, emergency department, or postanesthesia setting. Its administration is indicated in patients with coma of suspected toxic etiology, particularly when signs of opioid intoxication (e.g., miosis, hypoventilation) are present. The use of opioid antagonists is discussed in detail in the chapter on opioids. Their clinical pharmacology is described in ► [Chap. 157, “Opioid Receptor Antagonists.”](#)

Several clinicians have reported a clinical response to naloxone in patients with various nonopioid drug intoxications. Improvement in mental status after naloxone has been reported in the setting of ethanol, clonidine and related

imidazolines, valproate, and possibly even ibuprofen overdose [44–48]. The mechanism of this effect is unclear, but it is theorized that these agents have some degree of activity at the μ receptor. In clinical practice, however, response to naloxone with these overdoses has proved inconsistent, suggesting that in some cases the true mechanism may be one of coincidence, concomitant therapy, or nonspecific arousal.

Dosing practices for naloxone vary widely. An initial dose of 0.4–2.0 mg (0.01 mg/kg in pediatric patients) intravenously generally is recommended, although higher doses (10 mg) are needed in some cases [49, 50]. The therapeutic index of naloxone is remarkable; 4 mg/kg has been administered to volunteers without adverse effect [51]. Use of this agent is not totally without risk, however. Precipitation of withdrawal can be a significant obstacle to patient management. If opioid dependency is suspected, a lower starting dose (0.1–0.2 mg) should be used to minimize the risk of this complication [49]. Seizures also have been reported rarely [49]. Although intravenous infusion is the most common route of administration, naloxone is also effective when given subcutaneously, intramuscularly, endotracheally, or nebulized [52]. In fact, naloxone (both injectable and intranasal) is being increasingly utilized in the prehospital setting by non-health-care personnel [53]. Onset of action occurs in 1–2 min.

The elimination half-life of naloxone is 60–90 min, resulting in a duration of effect that may not extend beyond the duration of opioid toxicity. Naloxone-responsive patients must be monitored carefully because rebolus of naloxone may be required. In cases of intoxication with long-acting opioids (methadone, levomethadyl acetate), an option is to use a continuous naloxone infusion. One protocol recommends that two thirds of the response dose should be infused hourly [49]. A naloxone infusion always should be titrated to the desired clinical effect, however.

Nalmefene is a derivative of the opioid antagonist naltrexone, which differs in activity from naxolone only in its longer duration of action. The half-life of nalmefene after intravenous administration is 11 h [54]. The typically recommended dose is 0.5–1.0 mg/70 kg body

weight intravenously. In opioid-naïve patients, 0.5 mg/70 kg body weight can be given intravenously as an initial dose, followed 2–5 min later by a second dose of 1 mg/70 kg body weight, if needed. Doses over 1.5 mg/70 kg body weight are unlikely to be of further benefit. Clinical response is expected within 5 min. Although nalmefene administration may be advantageous in the setting of toxicity from a long-acting opioid, special consideration must be given to the disadvantages of routine use of this agent. Opioid withdrawal produced by nalmefene is protracted compared with naloxone [55, 56]. Additionally, emergency department discharge of substance abusers who are treated with nalmefene for opioid abuse is theoretically dangerous because the antagonist's persistent effects may compel the individual to use higher doses of illicit opioid to overcome the effect. If possible, diagnostic trials should be done with naloxone. If naloxone is unavailable, low-dose nalmefene (e.g., 1 mg) may be considered. Finally, substance abusers who receive nalmefene in the emergency department should be admitted for observation [55].

Flumazenil

The benzodiazepine receptor antagonist flumazenil may be useful for reversal of benzodiazepine-induced sedation after general anesthesia, procedural sedation, or overdose [43]. Flumazenil is a nonspecific competitive antagonist at the benzodiazepine receptor. The effectiveness of flumazenil is well documented [57–61]. Its use can confirm quickly a clinical diagnosis of benzodiazepine receptor agonist-induced decreased level of consciousness, obviating the need for time-consuming, expensive investigations and interventions in patients with altered mental status. In patients with pure benzodiazepine overdose, return to consciousness after flumazenil administration occurs within minutes. Its administration also results in faster return to baseline alertness in patients undergoing conscious sedation with benzodiazepines. It has also been used successfully in reversing coma due to newer hypnotics used for insomnia (i.e.,

zolpidem, zopiclone, and zaleplon) [62]. The intrinsic safety of flumazenil is remarkable; 100 mg intravenously has been given without significant adverse effects. Seizures and cardiac dysrhythmias have occurred after flumazenil administration, however [57, 58, 62–66]. In most cases, these effects are well tolerated and do not alter clinical outcome, but fatalities do occur [63]. Coingestion of drugs with proconvulsant properties (Table 9) is associated with an increased risk of seizure after flumazenil administration. This risk presumably is due to loss of the benzodiazepine’s protective anticonvulsant effect when the antagonist is administered. Combined overdose with tricyclic antidepressants accounts for 50% of these cases [56]. Other coingestants possessing proarrhythmic properties, such as carbamazepine and chloral hydrate, may increase the likelihood of cardiac effects by a similar mechanism [58]. Other risk factors contraindicating the use of flumazenil are summarized in Table 11. Using these criteria, stratification of patients into high-risk and low-risk categories can be done easily, but few patients are eligible for flumazenil if the criteria are strictly applied [67]. Nevertheless, flumazenil has been shown to safely reduce

the need for ventilatory support and extensive diagnostic studies in selected patients, even when coingestants were involved [66].

One common and important relative contraindication to flumazenil is regular use of benzodiazepines. Administering flumazenil to benzodiazepine-dependent patients may provoke severe benzodiazepine withdrawal, a condition that is characterized by agitation and potential seizures [68].

Although flumazenil has been shown to be effective in reversing benzodiazepine-induced sedation, it does not reverse respiratory depression consistently [69]. Because the duration of action of flumazenil is short (0.7–1.3 h), re sedation occurs in 65% of patients and requires either redosing or continuous infusion [57, 70, 71]. In patients undergoing conscious sedation, use of lower doses of benzodiazepines may reduce this risk [61]. Any patient who has reversal of CNS depression with flumazenil must be monitored closely for a minimum of 1 h for the possibility of re sedation.

The usual recommended initial adult dose of flumazenil is 0.2 mg intravenously over 30 s. A second dose of 0.3 mg may be given, followed by 0.5-mg doses at 1-min intervals, to a total dose of 3 mg. Most patients respond to less than 3 mg. In children, weight-based dosage of 0.01 mg/kg is recommended. Use of a continuous intravenous flumazenil infusion (0.25–1.0 mg/h) after a loading dose may maintain better overall consciousness but does not decrease the rate of complications arising from severe benzodiazepine toxicity [71].

Because of the aforementioned potential adverse effects, flumazenil should not be used indiscriminately in all patients with altered mental status. Flumazenil should not be used in place of standard support measures, including airway control, gastrointestinal decontamination, and hemodynamic stabilization. The clinical pharmacology of flumazenil is described in detail in ► Chap. 148, “Flumazenil.”

Table 11 Use of flumazenil

Indications
Isolated benzodiazepine overdose in a nonhabituated user
Reversal of procedural sedation
Contraindications
<i>Absolute</i>
Known or suspected coingestant that lowers seizure threshold:
Tricyclic antidepressants, cocaine, amphetamines, lithium, methylxanthines, isoniazid, tramadol, MAO inhibitors, bupropion, velafaxine, diphenhydramine, carbamazepine, GHB, PCP
Chronic (habituated) benzodiazepine user
Active sedative–hypnotic and/or alcohol withdrawal
Seizure activity or myoclonus already present
Hypersensitivity to flumazenil
Patient with neuromuscular blockade
<i>Relative</i>
Head injury
Panic attacks
Known seizure disorder
Alcoholic patients

Physostigmine

Physostigmine is a short-acting acetylcholinesterase inhibitor used to reverse toxicity from

anticholinergic agents. By competing with acetylcholine for metabolism via this enzyme, physostigmine effectively increases the concentration of acetylcholine in the synapse. The higher concentration of acetylcholine overcomes competitive postsynaptic muscarinic receptor blockade produced by anticholinergic agents. Use of physostigmine should be considered in the presence of signs and symptoms of anticholinergic toxicity, including tachycardia, fever, mydriasis, anhidrosis, gastrointestinal hypomotility, urinary retention, and altered mental status (Table 12). Other acetylcholinesterase inhibitors – pyridostigmine, neostigmine, and edrophonium – are ineffective due to an inability to penetrate the blood–brain barrier [72]. The anticholinergic syndrome is discussed in detail in ► Chap. 23, “Anticholinergic Syndrome.”

Use of physostigmine in the appropriate setting of severe anticholinergic toxicity may have advantages over supportive care alone [73]. Clearing of signs of toxicity after administration of this antidote confirms the diagnosis and may obviate the need for an intensive workup for altered mental status. Respiratory depression from severe intoxication may be reversed, avoiding the need for advanced airway management. Finally, a study suggested that physostigmine may control anticholinergic-induced agitation and delirium more adequately than benzodiazepines, which

currently are the preferred agents to manage agitation in this setting [70]. Multiple doses of physostigmine were required in 58% of the patients, with side effects occurring in 11% [70]. Nevertheless, clinicians considering the use of physostigmine must have a thorough understanding of its pharmacologic effects and risks of its use. Administration of physostigmine in the absence of actual anticholinergic toxicity may produce cholinergic effects. Seizures after physostigmine administration have been reported, especially when concomitant intoxication with substances known to lower the seizure threshold has occurred [74]. Several drugs associated with seizures in overdose, such as tricyclic antidepressants, carbamazepine, and phenothiazines, also have anticholinergic effects that may render a misleading picture of pure anticholinergic overdose. Physostigmine has a parasympathomimetic effect, increasing vagal tone, which can lead to bradydysrhythmia. Asystole has been reported after use of physostigmine in a patient with poisoning from a tricyclic antidepressant [75], although the asystole may have resulted from the tricyclic ingestion itself. Physostigmine has been shown to be safe and effective in large series and case reports when used appropriately [76–78].

The use of physostigmine also has been reported to result in arousal of a series of patients with coma due to gamma hydroxybutyrate (GHB) intoxication [79]. The proposed, although unvalidated, mechanism is nonspecific CNS arousal. Two of the three patients in this series manifested cholinergic symptoms. Physostigmine should not be used routinely in cases of suspected intoxication by GHB or its congeners because of the risks of unrealized coingestants or precipitation of cholinergic symptoms (including emesis with risk for aspiration) [79]. GHB intoxication generally resolves without sequelae after a few hours of supportive care and airway protection [80, 81]. Intoxication with GHB or its congeners is discussed in detail in ► Chap. 76, “Gamma-Hydroxybutyrate and Its Related Analogues Gamma-Butyrolactone and 1,4-Butanediol.”

The usually recommended dose of physostigmine is 2 mg in adults or 0.02 mg/kg in children. Rapid intravenous bolus administration can be dangerous; slow infusion over approximately

Table 12 Agents with anticholinergic effects

Antihistamines: diphenhydramine, doxylamine, cyproheptadine, hydroxyzine, brompheniramine
Antispasmodics: oxybutynin, hyoscyamine, atropine
Ipratropium bromide
Scopolamine
Diphenidol
Phenothiazines
Ophthalmic cycloplegics
Antiparkinsonian agents
Tricyclic antidepressants
Pirenzepine
Carbamazepine
Pizotifen hydrogen maleate
Botanicals: jimsonweed, deadly nightshade, angel’s trumpet, black henbane, Paraguay tea, <i>Amanita muscaria</i> (mushroom)

2–4 min generally is recommended. Onset of the effect may be delayed for 10–15 min. Signs and symptoms of toxicity may recur because the duration of action of physostigmine is only 20–60 min. Repeated doses are not usually necessary [74]. Some patients with otherwise hard-to-control anticholinergic delirium may benefit from repeat administration; however, it is not usually required to treat acute anticholinergic-based plant toxicity (usually related to *Datura stramonium*) [82]. The clinical pharmacology of physostigmine is discussed in detail in ► Chap. 161, “Physostigmine.”

Lipid Emulsion Therapy

Administration of intravenous lipid emulsion has been increasingly utilized in the resuscitation of local anesthetic, antidepressant, and cardiovascular drug cardiac toxicity [83]. Additionally, published case reports record reversal of toxicity from other lipophilic drugs, such as quetiapine, sertraline, lamotrigine, and olanzapine [84]. It has been demonstrated to improve Glasgow Coma Scale scores due to nonlocal anesthetic drug intoxication in young adults [85].

The dosage and administration of lipid emulsion antidotal therapy is further discussed in ► Chap. 152, “Lipid Resuscitation Therapy.”

Management of the Agitated Patient

Management of patients with violent behavior or agitation due to intoxication is often challenging to the clinician. Verbal attempts to de-escalate violent behavior in the intoxicated patient should remain the first approach, as should evaluation and treatment of any medical condition (e.g., hypoxia, pain) that may be contributing to the agitation. If these measures fail, use of restraint may be considered. Physical restraint of violent patients with intoxications causing hyperadrenergic states or seizures (e.g., cocaine, amphetamines, phencyclidine, withdrawal from ethanol or benzodiazepines) may be dangerous, particularly if inadequate sedation is given. Pharmacologic

management (i.e., “chemical restraint”) also may be employed, but the clinician must remain mindful of potential side effects or drug interactions. Antipsychotics and benzodiazepines are the two most commonly used agents in this setting.

The butyrophenones (e.g., haloperidol) have traditionally been the preferred antipsychotic agents because they manifest fewer anticholinergic and quinidine-like effects compared with the phenothiazines (e.g., chlorpromazine). Haloperidol has been shown repeatedly to be a safe and effective drug for acute control of agitation [86]. The commonly recommended dose is 5–10 mg deep intramuscularly (into the gluteal region) or intravenously every 10–30 min, titrated to the desired effect. Extrapyramidal side effects, such as dystonia or akathisia, may occur in up to 16% of patients and should be treated with either benztropine, 1–4 mg intravenously or intramuscularly, or diphenhydramine, 50 mg (0.5–1 mg/kg in pediatric patients) intravenously or intramuscularly. Although the use of haloperidol has been shown to lower seizure threshold in animals, there are no reports of seizures clearly induced by haloperidol in humans. Droperidol differs from haloperidol in its faster onset of effect, shorter half-life, more pronounced sedation, and lower incidence of extrapyramidal side effects. Transient orthostatic hypotension has been reported after its use. The commonly recommended dose of droperidol is 2.5–10 mg intramuscularly.

Ziprasidone is an atypical antipsychotic agent often used to control agitation. It is a serotonin (5-HT_{2A}) and dopamine (D₂) receptor antagonist. Weaker dopamine receptor effects result in fewer extrapyramidal effects compared with haloperidol. Prolongation of the QT/QT_c interval on ECG may occur in a dose-related manner, but clinically relevant prolongation is rare (0.06%). Its dose is 10 mg every 2 h intramuscularly (or 20 mg every 4 h) to a maximum daily dose of 40 mg [87, 88].

Benzodiazepines are the agents of choice in patients with ethanol or benzodiazepine withdrawal or in patients with hyperadrenergic states from sympathomimetic agents. Although many benzodiazepines have been shown to be effective, lorazepam has been studied most extensively. The usual recommended dose of lorazepam is 2–4 mg

intravenously. Some studies suggest that combination therapy with a benzodiazepine plus an antipsychotic may control violent behavior more effectively [86]. Intravenous dexmedetomidine (0.2 ug/kg/h initial dose followed by titration doses up to 0.7 ug/kg/h titration) or low-dose ketamine (0.2 mg/kg/h) appears to reduce benzodiazepine requirements as an adjunctive agent in treating the alcohol withdrawal syndrome [89, 90]. It should be noted that dexmedetomidine cannot be used in patients with heart block [88].

New alternatives to benzodiazepines in treating withdrawal delirium include phenobarbital, either orally or intravenously (up to 2000 mg on day 1, although at not more than 400 mg/dose), carbamazepine (approximately 800 mg per day), or oxcarbazepine (approximately 900 mg per day) [91]. Patients unresponsive to high doses of benzodiazepines usually respond to propofol after intubation (dose 0.3–1.25 mg/kg intravenously up to 4 mg/kg/h for up to 48 h) [91]. To avoid precipitating Wernicke's encephalopathy, higher doses of thiamine should be utilized (500 mg intravenously, three times daily for 5 days) along with daily parenteral multivitamins [92, 93].

The routine use of thiamine (100 mg daily orally for up to 30 days) has been recommended in combination with benzodiazepines in treating any severity of alcohol withdrawal [93].

Patients with drug-induced or toxin-induced alterations in consciousness require close monitoring. Progressively worsening intoxication may lead to profound CNS depression and airway compromise. The propensity for these conditions to occur may be increased by the use of pharmacologic agents to achieve behavior control and sedation. Seclusion should never be employed unless some method of continuous observation (e.g., video monitoring) can be arranged.

Prognosis

Generally, recovery from coma due to a toxic cause is much better than that from an anoxic cause. Mortality of coma due to a sedative drug intoxication is less than 1% [94]. Table 13 presents prognostic signs of worsening of coma and

Table 13 Poor neurologic prognostic signs for recovery from toxic coma

Loss of pupillary reflexes (up to 1 week)
Absence of corneal reflexes after day 1
Lack of oculovestibular response
Absence of eye-opening response at day 3
Absence of bilateral cortical component of somatosensory evoked potential responses
Abnormal skeletal muscle tone
Absence of spontaneous eye movement
Low-voltage delta activity (with alpha coma) or isoelectric tracing on electroencephalogram

Data from Adams et al. [3]

poor outcome [2, 95]. Although these prognostic indicators generally have been studied in patients with hepatic encephalopathy, they seem to be a reasonable guideline for patients with a toxic cause of coma. Patients taking agents described in Table 3 resulting in cyclic coma can exhibit a full recovery despite these prognostic signs [94, 96]. Full recovery from prolonged coma and loss of brainstem reflexes has been described after amitriptyline and doxepin overdose [97, 98]. Short-term memory deficits and amnesia after coma usually are due to injury of the pyramidal neurons of the hippocampus (CA 1 subfield) and are possible sequelae of an anoxic injury or carbon monoxide toxicity [99].

Seizures are a common feature of high-dose and, in some instances, minor or therapeutic exposure to a variety of drugs, chemicals, and toxins. It is estimated that 6.1% of new-onset seizures could be drug related [1].

In a prospective study of critically ill medical patients, seizures were found to be second only to metabolic encephalopathy as the most common neurologic complication encountered [2]. In addition to exhibiting a direct, dose-dependent relationship to exposure to various substances, seizures are characteristic of withdrawal from numerous drugs and chemicals with CNS-depressant effects. Seizures may occur as a paradoxical effect of anticonvulsant medications, particularly after overdose or in seizure-prone individuals on accepted therapeutic regimens of these medications [3, 4].

Classes of agents frequently implicated in drug-induced, chemical-induced, and toxin-induced seizures (hereafter collectively referred to in this chapter as *toxicant-induced seizures* or *toxicant-induced convulsions*) include antidysrhythmics, anticonvulsants, antidepressants, antihistamines, antipsychotics, antimicrobials, antiasthmatics, antineoplastics, CNS stimulants, local anesthetics, opioid analgesics, sedative-hypnotics/alcohol (withdrawal), metals (e.g., lead, alkylmercury), pesticides (e.g., insecticides, rodenticides), and certain alcohols [5]. Table 1 provides a more complete listing, by functional class, of agents with proconvulsant potential.

This chapter is a revision of the chapter on this topic by Kevin Wallace in the first edition of this text. Much of the material herein was contained in the chapter in the first edition.

Table 1 Proconvulsant agents: classification by source and use

Class	Example(s)
Pharmaceuticals	
Analgesics	Meperidine/normeperidine, propoxyphene, pentazocine, salicylate, tramadol
Anesthetics	Local anesthetics (lidocaine, benzocaine)
Anticonvulsants	Carbamazepine
Antidepressants	Tricyclics (amitriptyline/nortriptyline), amoxapine, bupropion, SSRIs (citalopram), venlafaxine
Antihistamines	Diphenhydramine, doxylamine, tripeleennamine
Antimicrobials	Antibacterials (selected penicillins, cephalosporins, carbapenems, and fluoroquinolones), antimalarials (chloroquine), tuberculostatics (isoniazid)
Antineoplastics	Alkylating agents (chlorambucil, busulfan)
Antipsychotics	Clozapine, loxapine
Asthma medications	Theophylline
Cardiovascular drugs	Propranolol, quinidine
Cholinergics	Pilocarpine, bethanechol
Muscle relaxants	Baclofen, orphenadrine
NSAIDs	Mefenamic acid, phenylbutazone
Psychostimulants/anorectics	Amphetamine, caffeine, cocaine, methamphetamine, MDMA, synthetic cannabinoids
Vitamins/supplements	Vitamin A, iron salts (ferrous sulfate)
Nonpharmaceuticals	
Alcohols	Methanol, ethanol (withdrawal)
Antiseptics/preservatives	Ethylene oxide, phenol
Biologic toxins	
Marine animals	Domoic acid (shellfish [blue mussels])
Mushrooms	Monomethylhydrazine (<i>Gyromitra</i> spp.)
Plants	Coniine (poison hemlock), virol A (water hemlock), camphor

(continued)

Table 1 (continued)

Class	Example(s)
Gases (naturally and/or anthropogenically occurring)	Carbon monoxide, hydrogen sulfide, hydrogen, cyanide
Metals/organometallics	Alkyl mercurials (dimethylmercury), arsenic, lead, thallium, tetraethyl lead, organotins (trimethyltin)
Metal hydrides	Pentaborane, phosphine
Pesticides	
Fungicides/herbicides	Dinitrophenol, diquat, glufosinate
Insecticides	Organochlorines (lindane, DDT), organophosphates (parathion), pyrethroids (type II), sulfuryl fluoride, alkyl halides (methyl bromide)
Molluscacides	Metaldehyde
Rodenticides	Strychnine, zinc, or aluminum phosphide

MDMA 3,4-methylenedioxymethamphetamine, *NSAIDs* nonsteroidal anti-inflammatory drugs, *SSRIs* selective serotonin reuptake inhibitors

Toxicant-induced convulsions, given the typically diffuse CNS distribution of proconvulsant substances and their highly specific neurochemical mechanisms, usually are generalized. They may be prolonged, recurrent, or both; they meet clinical and mechanistic definitions for status epilepticus (SE) [6], and they may be remarkably refractory to widely recommended antiepileptic drug regimens. Definitions of SE, a condition of prolonged or recurrent seizure activity without interictal awakening, have incorporated critical time intervals for continuous seizure activity that range from 5 [2, 6] to 30 min [7]. Although there is little evidence to support these temporal cutoffs as thresholds beyond which seizure-induced CNS injury occurs, these definitions emphasize the apparent direct relationship between duration of seizure activity and clinicopathologic outcome and the paramount importance of anticonvulsant therapy in the management of sustained seizure activity.

Conservative estimates of the incidence of SE in the United States range from 60,000 to 160,000

patients per year [7, 8]. The mortality associated with SE since the 1980s has been observed to be higher in adults (15–22%) than in children (3–15%) and greater than 10% if caused by drug toxicity [9]. Extremes of age and seizure duration of greater than 1 h have been predictive of poor outcome [6]. In published case series of SE patients, the reported proportions of cases judged to be of toxic etiology (ethanol or drug related) range from 2.4% in patients younger than 16 years old [7] to 24% in older alcoholic individuals [6].

Subtle [10] and *nonconvulsive* are descriptive terms that have been used to denote less than obvious or subclinical SE (i.e., ongoing electrical seizure activity shown by electroencephalography [EEG] with or without subtle convulsive movements, such as rhythmic muscle twitches or tonic eye deviation). Nonconvulsive SE, which may occur after pharmacologic neuromuscular blockade, has been an underrecognized cause of altered consciousness or behavior [11], with coma at the time of diagnosis of SE predictive of fatal outcome [12]. In a study of 236 patients (age range 1 month to 87 years) with coma and no overt clinical seizure activity, 8% had at least 30 min of continuous electrographic seizure activity [13].

The mortality rate associated with subtle SE in a multicenter trial comparing four drug treatments for generalized convulsive SE was 65% versus 27% in patients with overt SE. Longer hospital stays also were associated with subtle SE [10]. There may be a rational basis for the concern that neuronal injury resulting from unrecognized subclinical SE is of equal or even greater severity than that occurring as a result of overt clinical SE. Understanding of the pathophysiology and prognosis of nonconvulsive SE is limited, however, by the current lack of controlled comparative data, difficulties with case definition, confounding factors (e.g., underlying neurologic disorder), and the highly anecdotal nature of available clinical data [9, 14].

The main objectives of this chapter are to provide a rational mechanistic approach to the evaluation and treatment of toxicant-induced convulsions. Emphasis is on the importance of considering nontoxic and primarily toxic causes of seizures and of employing an aggressive and

more selective approach to anticonvulsant treatment than might be indicated in seizures of nontoxic origin.

Epidemiology

The leading causes of drug-induced seizures may vary over time. It is important for the clinicians to be aware of the evolving changes in prescribing patterns to better predict which toxic substances may be responsible for serious complications. The trends of drug-related seizures may be estimated from the data reported to the poison control centers.

In 1994, Olson and colleagues [15] observed that in 191 cases of seizures associated with poisoning and drug overdose reported to a West Coast US regional poison control center, the most commonly implicated agents or class of agent were cyclic antidepressants (29%), cocaine (22%), diphenhydramine (7%), theophylline (5%), isoniazid (5%), and methamphetamine/amphetamine (3%).

In a retrospective review of all calls to the California Poison Control System in 2003, the leading causes of seizures were bupropion (23%), diphenhydramine (8.3%), tricyclic antidepressants (7.7%), amphetamines (6.9%), isoniazid (5.9%), and venlafaxine (5.9%) [16]. In comparison with a similar study performed in 1993, there was a significant increase in recent antidepressant-related seizures, but a decrease of tricyclic antidepressant- and cocaine-related seizures. In the majority of the cases, seizures were limited to a single episode, while SE remained a rare complication (3.6%). Seizures were mostly the consequence of suicide attempts and 14.8% resulted from drug abuse. Death observed in a limited number of cases was more likely to occur in patients who were exposed to stimulants.

A study conducted by the Swiss Toxicological Information Centre between January 1, 1997, and December 31, 2010, examined which pharmaceutical exposures were commonly associated with overdose-induced seizures [17]. Among 15,441 single-agent exposures, seizures occurred in 313 cases. The most prevalent pharmaceuticals

were mefenamic acid (51), citalopram (34), trimipramine (27), venlafaxine (23), tramadol (15), diphenhydramine (14), amitriptyline (12), carbamazepine (11), maprotiline (10), and quetiapine (10). The seizure potential of a pharmaceutical was calculated by dividing the number of cases with seizures by the number of all cases recorded with that pharmaceutical. Drugs with a high seizure potential were bupropion (31.6%), maprotiline (17.5%), venlafaxine (13.7%), citalopram (13.1%), and mefenamic acid (10.9%). The probability of seizures with mefenamic acid, citalopram, trimipramine, and venlafaxine increased as the ingested dose increased. Considering the different age groups, it appeared that adolescents might be more susceptible to seizures after mefenamic acid overdose than adults.

With the increasing use of tramadol as analgesic, seizures are also becoming more frequently reported, not after chronic tramadol therapy (except for co-ingestants or individual susceptibility factors), but particularly in overdose. In a series of 525 intentional tramadol exposures, 46.1% of the patients developed seizures (single episode in 88.1%, recurrent seizures in 11.9%) [18]. This is also in accordance with the results of a previous prospective observational study conducted on 401 patients, where the incidence of seizures was 30.2% [19]. The mean ingested dose was 1511 mg, and 200 mg was the lowest dose associated with seizure. Seizure activity appeared to be dose dependent, but no significant correlation was found with tramadol blood concentrations. Seizures are usually described as brief, self-limiting, and most often occur within 4–6 h post-ingestion.

More recently, special attention has been given to synthetic cannabinoid receptor agonists (which are discussed in detail in a separate chapter on these agents) due to their wide availability from the Internet, and seizures have been reported following recreational exposure [20–23].

In summary, these epidemiological data illustrate the changes of pharmaceutical and nonpharmaceutical exposures responsible for seizures, with progressive shifts within the classes of substances (antidepressants, analgesics,

recreational drugs). Recent trends have highlighted the prominent role of SSRIs, bupropion, tramadol, and synthetic cannabinoids with a progressive decline of tricyclic antidepressants and cocaine.

Pathophysiology

According to Schaumberg [24], “The nature of the discharging lesion in toxin-induced seizures presumably is different in some respects from the lesion in most epileptic patients; the toxin-induced seizure usually originates in previously normal neurons, while the patient with epilepsy frequently has a focus in an abnormal cortical area.” Other authorities on epilepsy note that the pathophysiology of posttraumatic or idiopathic seizures is characterized by the spread of electrical activity from a relatively isolated focus to neighboring cortical regions when the intensity of seizure discharge overcomes the inhibitory influence of surrounding neurons [25]. In contrast, toxicant-induced seizures involve simultaneous increases in electrical discharge from susceptible neuronal populations in response to toxicant-induced neurochemical or other functional (e.g., metabolic) derangements or both.

Proconvulsant substances exert their neurotoxic effects through a variety of postulated mechanisms, for which there are a growing abundance of supporting experimental data [26]. A common theme that applies to most of these proconvulsant mechanisms is that in some manner they give rise to an imbalance in the normal neurochemical homeostasis of the central nervous system (CNS) (i.e., they cause a disturbance in the balance between excitatory and inhibitory neurotransmission). This imbalance can result from increased excitatory tone, decreased inhibitory tone, or both, leading to a diffuse increase in neuronal excitability in typically dose-dependent fashion beyond the physiologic threshold for seizure activity. The remainder of this section focuses on the role that several major CNS neurotransmitter systems play in the genesis of toxicant-induced convulsions.

Gamma-Aminobutyric Acid (GABA) Antagonism

GABA is the principal inhibitory central neurotransmitter, present in an estimated 30% of all central synapses. Substances that antagonize GABA activity produce CNS excitation and convulsions. Paradoxically, GABA is synthesized in the brain through the actions of glutamic acid decarboxylase on glutamate (Fig. 1), the brain's main excitatory neurotransmitter.

GABA is stored in vesicles in presynaptic nerve terminals and is released into synapses in the brain and spinal cord via calcium (Ca^{2+})-dependent exocytosis. There are two main subtypes of transmembrane polypeptide receptors that bind GABA, designated GABA_A and GABA_B .

Antagonism of GABA_A receptors has been implicated most frequently in the proconvulsant actions of drugs, chemicals, and toxins. The GABA_A receptor complex (Fig. 2) is a ligand-gated

chloride (Cl^-) channel that is integral to the postsynaptic neuronal membrane. When GABA binds to its receptor site on the complex, it triggers postsynaptic Cl^- influx, which results in membrane hyperpolarization and a decrease in postsynaptic neuronal excitability and impulse propagation (see Fig. 1) [31].

In addition, the $\text{GABA}_A \text{Cl}^-$ channel has multiple binding sites for exogenous and endogenous modulatory agents, including excitatory/proconvulsant drugs (e.g., penicillin, amoxapine, maprotiline [32–34]) and depressant/anticonvulsant drugs (e.g., benzodiazepines, barbiturates), which produce their actions through allosteric conformational enhancement or impairment of Cl^- influx in response to GABA binding [35]. Most of these drugs require that GABA itself bind to its receptor site on the GABA_A complex for inhibitory or excitatory effects to occur and are termed *indirect* agonists and antagonists. Substances that exert their effects on the GABA_A chloride ionophore by directly binding to

Fig. 1 Presynaptic and postsynaptic elements. *ap* action potential, *Gad* glutamic acid decarboxylase, *EC* extracellular, *IC* intracellular, *ipsp* inhibitory postsynaptic potential (From Brody et al. [27], p. 367)

Fig. 2 Generic GABA_A receptor protein subunit sequence and putative topologic structure. The numbering follows that of the rat α_1 sequence used by Khrestchatsky and colleagues [28]. Note the NH₂ terminal (labeled N, residue 1) presumed extracellular domain, with probable sites for asparagine glycosylation (polymeric black circles at positions 10 and 110), and the cystine bridge (solid line connecting 138 and 152). Four putative membrane-spanning α -helical cylinders M1, M2, M3, and M4 are shown. The COOH-terminus (labeled C, residue 428) is

extracellular. A large intracellular cytoplasmic loop between M3 and M4 is present. The shading indicates the degree of variability within the family of rat polypeptides published to date: α_1 , α_2 , α_4 , β_1 , β_2 , β_3 , γ_2 , and δ . Amino acids that are identical in all the clones are shown in white; amino acids identical in two or more types are light gray; amino acids identical in all α but not in β , γ , and δ are black; and amino acids that vary between types are dark gray (A from Smith and Reynard [29]. B from Olsen and Tobin [30])

the GABA receptor locus are termed *direct* agonists (e.g., muscimol) and antagonists (e.g., bicuculline).

Reduction in GABAergic neuroinhibitory tone also results from inhibition of GABA synthesis, such as that produced by isoniazid and other hydrazine compounds. Isoniazid lowers CNS GABA concentrations by several mechanisms, the main one being competitive inhibition of pyridoxine kinase, which results in depressed synthesis of pyridoxal phosphate, a cofactor needed for glutamic acid decarboxylase activity and GABA synthesis (see Fig. 1). Other mechanisms include direct inhibition of glutamic acid decarboxylase and increased urinary excretion of pyridoxine [36, 37].

Human and experimental data support direct and indirect antagonistic actions at the GABA_A

complex as the basis for the epileptogenic effects of members of several classes of antibiotics (penicillins, cephalosporins, carbapenems, and fluoroquinolones) [38], organochlorine compounds such as lindane and cyclodiene insecticides (e.g., dieldrin) [39], various antidepressants [32–34], and virol A, a long-chain alcohol found in *Cicuta virosa*, a species of water hemlock [40]. Penicillin has been distinguished from other GABA antagonists on the basis of its multiple mechanisms of effect at GABA_A chloride channels, including direct actions within the chloride channel itself (i.e., independent of its direct and indirect GABA-agonist actions) [38]. In addition, cefazolin, a first-generation cephalosporin antibiotic, and pentylentetrazol, an analeptic compound

that binds to the picrotoxin-binding site on the GABA_A complex and is used widely in experimental epilepsy research, contain tetrazole moieties and are potent proconvulsants, consistent with a common structure–activity relationship.

Increases in the ratio of central neuroexcitatory to neuroinhibitory tone, resulting in convulsive activity, also can occur as a result of abrupt GABA-agonist withdrawal after a chronic exposure period of sufficient duration to produce pharmacodynamic tolerance by downregulating GABA_A functional expression (see ► Chap. 45, “Anxiolytics, Sedatives, and Hypnotics”). Agents that possess GABA_A-agonist properties include ethanol, various benzodiazepines and barbiturate sedative–hypnotics, carisoprodol, meprobamate, zolpidem, and propofol. GABA_B receptors are metabotropic transmembrane receptors for GABA that are linked via G-proteins to potassium channels. GABA_B receptors are involved in behavioral actions of ethanol, gamma-hydroxybutyric acid (GHB), and gamma-butyrolactone (GBL).

Glycine Antagonism

Another type of neuroinhibitory ligand-gated ionophore, the glycine-gated chloride channel, has a well-established role in modulating efferent motor neuron activity at the level of the lower brainstem and spinal cord. Glycine functions as a postsynaptic inhibitory neurotransmitter in a manner that is analogous to GABA at GABA_A chloride channels and prevents excessive lower motor neuronal electrical impulse propagation and reflex arc activation in response to afferent excitatory input. Strychnine antagonizes glycine’s actions at these postsynaptic inhibitory chloride channels in the spinal cord and brainstem, resulting in polysynaptic motor neuronal disinhibition and subsequent increase in motor tone and convulsive activity (“spinal convulsions”) (see ► Chap. 95, “Rodenticides”) [41].

Glutamate Agonism

As previously noted, glutamate is the main CNS excitatory neurotransmitter. It is synthesized in

presynaptic nerve terminals from α -ketoglutarate or glutamine and released from storage vesicles as a result of the influx of calcium through voltage-gated presynaptic calcium channels in response to propagated electrical impulses. Its postsynaptic actions are mediated through receptor sites on ligand-gated Ca²⁺ channels that also have binding sites for other ligands, including glycine and *N*-methyl-D-aspartate (NMDA). When open, these NMDA-glutamate Ca²⁺ channels also permit sodium (Na⁺) influx and, in some cases, potassium (K⁺) efflux (Fig. 3). The pathophysiologic consequences of these transmembrane ion fluxes are postsynaptic neuronal membrane depolarization and enhanced electrical excitability and neuronal cytotoxicity as a result of increases in intracellular Ca²⁺ concentration. The clinical effects are agitation/seizures and persistent neurologic functional impairment [42, 43].

Proconvulsant substances that have direct agonist and neuroexcitatory actions at NMDA-glutamate receptors include the marine toxins, domoic acid and kainic acid [44, 45], and glufosinate, a broad-spectrum herbicide [46]. Chronic administration of NMDA-glutamate receptor antagonists (e.g., ethanol, meprobamate), which exert more potent anticonvulsant effects than GABA_A agonists in some experimental models, results in upregulation of glutamatergic neurotransmission and pharmacodynamic tolerance to the sedative effects [47, 48]. Abrupt discontinuation of these agents is thought to result in increased NMDA-glutamate receptor complex-mediated ion flux, enhanced neuronal excitability, and increased risk of convulsions [43, 49]. This is combined with evidence supporting ethanol’s actions at GABA_A chloride channels, strongly suggesting a dual and concordant effect of ethanol on the balance between excitatory and inhibitory neurotransmission.

Acetylcholine (Muscarinic) Agonism

Although their clinical importance is uncertain, other excitatory neurotransmitter systems are postulated to play a role in the proconvulsant actions of a variety of toxicants. The proconvulsant

Fig. 3 Suggested components of glutamate receptors in the central nervous system. Channel shown in resting stage. Depolarization by agonist binding or voltage gating releases blockade by magnesium ions and lets potassium ions pass outward and Na^+ and Ca^{2+} pass into the nerve cell. Glycine acts to augment agonist effect (From Brody et al. [27], p. 18)

effects of the muscarinic agonist pilocarpine, used in experimental models of human epilepsy [50, 51], and the observation that stimulation of brain muscarinic receptors causes persistent tonic-clonic convulsions [52] suggest enhancement of muscarinic neurotransmission as a mechanism of induction of seizure activity by agents that inhibit neural acetylcholinesterase (e.g., organophosphate insecticides). It also has been suggested, however, that secondary GABAergic and glutamatergic mechanisms may be involved more directly in seizure production by these agents [53].

Adenosine Antagonism

A third major mechanism of proconvulsant action involves interference with the normal modulation of presynaptic excitatory neurotransmitter (e.g., glutamate) release. Substantial evidence implicates adenosine as an endogenous anticonvulsant substance that is “released during seizure activity, exerts stabilizing effects on the epileptogenic focus and surrounding neural tissues and the accumulation of which terminates seizure activity while increasing the threshold for further seizure induction” [54]. Prolonged clinical and electrographic seizure activity occurs when the anticonvulsant actions of adenosine are antagonized, as occurs with excessive doses of xanthine derivatives, such as theophylline or caffeine [55].

Adenosine is released from the presynaptic nerve terminal in the brain along with other neurotransmitters, such as glutamate, then binds to G-protein-coupled receptors on the same presynaptic terminal. The effect of stimulation of these so-named A_1 subtype adenosine receptors is a decrease in voltage-gated Ca^{2+} influx and inhibition of further presynaptic excitatory neurotransmitter release. When involved in negative feedback modulation of this sort, receptors commonly are referred to as *autoreceptors* (Fig. 4).

Adenosine-mediated spontaneous arrest of seizure activity is characterized by its alternating synaptic accumulation and clearance and is reflected in the ictal–interictal cycling that occurs during SE [55]. In addition, stimulation of a second adenosine receptor subtype, A_2 , located on cerebral blood vessels, results in vasodilation and a compensatory increase in cerebral blood flow during times of increased oxygen and nutrient requirements (e.g., during seizure).

Adenosine’s anticonvulsant activity has been shown convincingly in experimental studies of its effects on seizures induced by adenosine antagonists, such as theophylline [56]. Many other drugs have been found to alter the excitatory/inhibitory neurotransmitter balance through their effects on synaptic adenosine levels or more direct actions at adenosine receptors. There is evidence that benzodiazepines enhance neuroinhibitory tone, in part, through inhibition of presynaptic adenosine

Fig. 4 Presynaptic inhibition of excitatory neurotransmitter releases by adenosine. Agonism of the presynaptic inhibitory (also known as *autacoid*) A₁ receptor by

adenosine attenuates voltage-gated Ca²⁺ release, reducing the release of excitatory neurotransmitters (e.g., glutamate)

reuptake [54], whereas carbamazepine exhibits dose-dependent agonistic and antagonistic actions on adenosinergic modulation of excitatory neurotransmitter release [54, 57–59].

Other Mechanisms

Other neurotransmitter system components and mechanisms are postulated to play a contributory role in the proconvulsant effects of various pharmacologic agents, but supporting data are limited (Table 2). These mechanisms include the following:

- Presynaptic and postsynaptic GABA_B receptors as loci of action responsible for seizures observed in the setting of baclofen overdose [60] and withdrawal [61, 62]
- Presynaptic nerve terminal potassium channel blockade (e.g., by 4-aminopyridine) [63, 64], resulting in membrane depolarization, opening of voltage-gated calcium channels, increased calcium influx, and increased release of excitatory neurotransmitters (e.g., acetylcholine)
- Central histaminergic (H₁) receptor antagonism by antihistaminergic drugs (see ► Chap. 42, “Antihistamines”) (although supporting experimental evidence for this as a proconvulsant mechanism of action of antihistamines is mixed [65])
- Neuronal sodium channel blockade-mediated inhibition of presynaptic GABA release (e.g., by local anesthetics, such as lidocaine and procaine [66]) or disinhibition of excitatory neurons [4], or both, as a basis for the paradoxical proconvulsant effects of anticonvulsants that possess sodium channel-blocking properties (e.g., phenytoin, carbamazepine) [3, 4, 67–69]

The mechanisms of seizure production of other proconvulsive agents less directly involve alterations in neurotransmitter balance and have more to do with effects on neuronal metabolism and maintenance of functional and structural integrity. These agents include the following:

- Mitochondrial poisons that impair cellular adenosine triphosphate synthesis by uncoupling oxidative phosphorylation (e.g., salicylate, dinitrophenol) or inhibiting cellular respiration (e.g., cyanide, carbon monoxide) [70–72]
- Agents that cause direct cytotoxic injury (e.g., alkylating agents, such as ethylene oxide and methyl bromide) [73]
- Agents that cause fluid/electrolyte and other metabolic disorders, including hyponatremia, as a consequence of syndrome of inappropriate antidiuretic hormone (e.g., carbamazepine), hypoglycemia (e.g., sulfonylurea compounds), hypoglycorrhachia and neuroglycopenia (e.g.,

Table 2 Mechanism of action of proconvulsant drugs and toxins

Presumptive mechanism	Examples of toxic agents ^a
Neurochemical effect	
GABAergic	
GABA _A antagonism	
Direct	Bicuculline, penicillin
Indirect	Lindane (and other organochlorines), amoxapine, maprotiline, tricyclic antidepressants, penicillin , type II pyrethroids, cephalosporins, fluoroquinolones, virol A (<i>Cicuta virosa</i> , water hemlock), avermectin analogues (ivermectin)
Depressed GABA production	Isoniazid , monomethylhydrazine, cyanide
GABA _B agonism (?)	Baclofen
Agonist tolerance/withdrawal	
GABA _A	Ethanol, benzodiazepines, barbiturates , carisoprodol, meprobamate, zolpidem
GABA _B	Baclofen, GHB, GBL
Glycinergic	
Antagonism (spinal cord)	Strychnine , picrotoxin
Agonism tolerance/withdrawal (brain NMDA-glutamate)	Ethanol
Glutamatergic agonism	Domoic acid, kainic acid , glufosinate
Adenosinergic antagonism	Theophylline, caffeine
Cholinergic agonism	
Acetylcholine release	Aminopyridines
Direct nicotinic receptor agonism	Nicotine (and other nicotinic alkaloids)
Direct muscarinic agonism	Pilocarpine, bethanechol alkaloids
Acetylcholinesterase inhibition	Organophosphates (sarin, diazinon)
Adrenergic agonism	Amphetamine, cocaine
Histaminergic antagonism	Diphenhydramine, tripeleminamine
Sodium channel blockade (membrane-stabilizing effect)	Local anesthetics, cocaine, propranolol, carbamazepine, phenytoin, diphenhydramine
Metabolic or cytotoxic effect	
Hypoglycemia	Insulin, sulfonylureas, disopyramide, pentamidine, ackee fruit
Hyponatremia (SIADH)	Carbamazepine, vinca alkaloids, chlorpropamide, phenothiazines
Direct mitochondrial dysfunction	
Uncoupling of oxidative phosphorylation	Salicylate, dinitrophenol
Cytochrome oxidase inhibition	Cyanide/cyanogens, carbon monoxide, hydrogen sulfide, iron, methanol/formate, azide (?), phosphine (?)
Krebs cycle inhibition	Arsenic, sodium monofluoroacetate
Cellular injury	
Nonspecific irritant/denaturant	Phenol
Alkylating injury	Busulfan, chlorambucil, ethylene oxide, methyl bromide, methyl chloride
Unknown	
	Bupropion, camphor, cicutoxin, chloroquine, gamma-hydroxybutyrate, pyrimethamine, quinine/quinidine, mexiletine, tocainide, lithium, mefenamic acid, phenylbutazone, normeperidine, pentazocine, propoxyphene, tramadol, nonionic radiopaque contrast agents (intravenous/intrathecal metrizamide, iopamidol, iophendylate), propylene glycol, ethylene glycol (?), metaldehyde, organotin, pentaborane

GABA γ -aminobutyric acid, *GBL* gamma-butyrolactone, *GHB* gamma-hydroxybutyrate, *NMDA* *N*-methyl-D-aspartate, *SIADH* syndrome of inappropriate diuretic hormone secretion

salicylate), and hypercalcemia (e.g., mithramycin)

- The neurotoxic mechanisms of action for a large array of proconvulsant substances, including camphor, metaldehyde, cicutoxin, organotins, pentaborane, and tramadol, are unknown. The reader is referred to Table 2 for a mechanistically based listing of various drugs, chemicals, and natural toxins that can induce seizures.

Pathophysiology of Neurologic Sequelae and Systemic Complications

The development of neurologic sequelae of toxicant-induced convulsions, particularly when seizure activity is prolonged, likely involves excessive NMDA-glutamate-mediated influx and intracellular accumulation of calcium, which triggers events (e.g., apoptosis) that result in cell death. The relative importance of this mechanism, compared with the hypoxic-ischemic injury that might occur as a result of simple asphyxiation, is supported by the experimental occurrence of neuronal injury well before cerebral demand for oxygen exceeds supply [9, 74]. Irreversible neuronal injury has been shown to occur within 1 h of the onset of seizure activity [7, 9], whereas cerebral blood flow and oxygenation increase dramatically during the initial phase of SE and do not decline significantly until after several hours of seizure activity [9].

Neuronal tissue necrosis, atrophy, and sclerosis can result from relatively prolonged seizure activity and tend to occur in areas of the hippocampus where NMDA-glutamate receptors are relatively concentrated. This tissue injury ultimately may result in the formation of an epileptic focus [9]. Cerebral edema, herniation, cerebral hypoperfusion, and brain death represent a common lethal sequence of events after severe, prolonged generalized SE.

Numerous other systemic complications may occur as a result of toxicant-induced convulsions, particularly when convulsions are prolonged [9, 75, 76]. Respiratory failure may occur as a result of central apnea, upper airway obstruction, aspiration, or noncardiogenic pulmonary edema

secondary to persistent elevation of pulmonary vascular pressure. The consequences of marked, diffuse increase in skeletal muscle contractions include hyperthermia (also may be centrally mediated); rhabdomyolysis, with attendant hyperkalemia and myoglobinuric renal injury; and metabolic acidosis from increased consumption of oxygen and energy reserves [77]. The hyperadrenergic tone of the convulsing individual is manifested clinically by hypertension, cardiac tachydysrhythmias, and initial hyperglycemia. Experimental and clinical evidence supports the notion that hyperthermia, hypoxia, hypotension, and cerebral hypoperfusion that occur during relatively prolonged convulsive activity exacerbate neuronal injury and promote continuation of seizure activity [74, 75].

Clinical Features

Toxicant-induced convulsions may occur with or without clinical “warning” symptoms (e.g., aura) or signs (e.g., altered mental status). Although seizures that occur after overdose of tricyclic antidepressant drugs commonly occur after decline in sensorium, seizures occurring as a result of acute supratherapeutic and, in some cases, therapeutic exposure to some agents (e.g., bupropion) may occur without an obvious clinical prodrome. With some extended release preparations, seizures may be delayed. In one study of bupropion XL overdoses, a seizure occurred in 32% of patients. Of the 32% of patients who experienced a seizure, the initial seizure was delayed more than 8 h after ingestion in 24% of cases [78].

Other agents for which the clinical onset of proconvulsant effect is characteristically rapid, abrupt, or without obvious warning include isoniazid [38], amoxapine, camphor, cicutoxin, cyanide, hydrogen sulfide, lidocaine, organochlorine insecticides such as lindane and toxaphene, and strychnine.

Most toxicant-induced seizures occur as generalized, tonic-clonic (“grand mal”) episodes [24], with the relatively rare exception of focal seizure activity in individuals with preexisting epileptogenic foci [25]. Myoclonus (brief

muscular contractions typically lasting <0.1 s [25] may be the most frequently documented convulsant effect of some agents, such as penicillin [79], normeperidine [80, 81], and selective serotonin reuptake inhibitors [82]. The convulsive episodes that occur as a result of strychnine's actions at inhibitory glycine-gated chloride channels in the spinal cord and lower brainstem are characterized by opisthotonos and tonic symmetric back and limb extensor spasm (spinal convulsions) without ictal or interictal change in sensorium. It is incumbent on the clinician to carefully distinguish between true seizure activity and abnormal motor activity resulting from voluntary and involuntary movement disorders, such as pseudoseizures, tremor, dystonia, akathisia, chorea, and athetosis (Table 3) [83].

As electrical seizure activity continues, the clinical features of such an episode may be more subtle or even absent [84]. The occurrence of nonconvulsive SE should be considered in an individual whose sensorium remains depressed after an overt convulsive episode. It has been estimated that at least 20% of SE episodes are nonconvulsive [2], with an estimated prevalence of nonconvulsive SE by electrographic case definition of 26% among comatose patients and those with subtle convulsive movements, such as "muscle twitches or tonic eye deviation" [10]. Nonconvulsive SE is even more likely to occur in the emergency department or intensive care unit than in other clinical settings, where pharmacologic masking of seizure activity frequently occurs owing to the use of neuromuscular blocking agents.

Seizure activity that is prolonged, recurrent, or refractory to initial treatment suggests poisoning by a member of a relatively select group of toxicants, notably theophylline, isoniazid, and certain older antidepressant drugs (e.g., amoxapine). This observation was reflected in the findings of Olson and colleagues [15], who reported in their series of nearly 200 toxicant-induced convulsive episodes the proportional occurrence of multiple or prolonged seizures (or both) after acute overdose of antidepressants (29%), theophylline (40%), and isoniazid (50%).

Few studies have looked at the specific complications of drug-induced seizures. It appears that

Table 3 Differential diagnosis of toxicant-induced seizures

Toxic neuromuscular disorders that may be mistaken for seizures
Serotonin syndrome ^a
Acute dystonia (butyrophenones)
Chorea (cocaine)
Akathisia (phenothiazines)
Strychnine ^b
Tetanus ^b
Neurotoxic scorpion envenomation (<i>Centruroides sculpturatus</i>)
Nontoxic causes of seizure disorders
Stroke (hemorrhagic, nonhemorrhagic)
Subarachnoid hemorrhage
Traumatic brain injury (contusion, hemorrhage)
Intracranial neoplasm
Intracranial infection (abscess, meningitis, encephalitis)
Metabolic/electrolyte disorder (hypoxemia, hypoglycemia, uremia, hyponatremia, hypernatremia, hypocalcemia, hypomagnesemia)
Idiopathic (epilepsy)

^aAlthough the neurologic presentation of serotonin syndrome commonly is limited to muscular rigidity and myoclonus, it also may include more clinically overt seizure activity

^bStrychnine-induced and tetanus-induced convulsions are mediated primarily by effects at the level of the spinal cord (hence the use of the term spinal convulsions to describe the seizure-like posturing and movements observed in the former) and are not considered true seizures

there is a relatively high risk of complications in patients admitted in the emergency department after drug-induced seizures in comparison with seizures from other etiologies. In a retrospective analysis dealing with 121 patients who presented seizures after toxic exposure, risk factors associated with morbidity and mortality were investigated [85]. Complications were divided in the following categories: prolonged hospital stay (>72 h), need for endotracheal intubation, status epilepticus, anoxic brain injury, or death. The impact of ten predictor variables on these outcomes was analyzed: gender, reason for exposure, substance type, primary decontamination method, initial antiepileptic medication given (after benzodiazepines), presence of initial acidosis, hyperthermia, rhabdomyolysis, hyperglycemia, or hypotension. In the multivariate analysis, three

predictors demonstrated statistically significant associations: stimulant exposure, initial acidosis, and hyperglycemia. It remains, however, difficult to affirm whether acidosis and hyperglycemia were true contributors to complications or merely a consequence of generalized seizures. The association between hyperthermia and morbidity or mortality has to be further investigated.

Olson and colleagues [15] also observed in their series of toxicant-induced convulsion cases that the most frequent complications were respiratory failure (34%), cardiac arrhythmias (22%), hypotension (16%), hyperthermia (7%), rhabdomyolysis (6%), and death (9%). Systemic complications typically are more severe and occur more commonly with prolonged seizure activity. Hyperthermia has been documented to occur in SE at case frequencies ranging from 28% to 79% [74]. Prolonged strychnine-induced convulsions in one reported case resulted in hyperthermia (peak body temperature 43 °C at 3 h postexposure), metabolic acidosis (initial arterial pH 6.55), acute rhabdomyolysis (peak serum creatine phosphokinase 359,000 mU/mL [5983 µmol/L] approximately 2 days later), and myoglobinuria with transient acute renal insufficiency (peak serum creatinine 3.7 mg/dL [327 µmol/L]) [86]. The same patient's clinical course subsequently was remarkable for diffuse weakness, severe myalgias, and transient upper and lower limb motor deficits consistent with acute, reversible compressive neuropathy. Postictal focal neurologic deficits of central origin may be transient (e.g., Todd's paralysis) or permanent in instances of irreversible cerebral insult.

Diagnosis

Patient History

Obtaining a detailed history is crucial to effective decision making in the treatment of patients who have had toxic exposure to proconvulsant agents. A search for information regarding witnessed or possible unwitnessed exposure should include currently prescribed or available medications,

nature of the occupational setting and presence of proconvulsant agents, and material evidence or history corroborating alcohol or illicit substance abuse. The presence of preexisting conditions, such as renal insufficiency, musculoskeletal disorders, epilepsy, and psychiatric illness, may lead to the early identification of a toxic convulsive etiology and prompt appropriate management decisions, including discontinuation of an offending pharmaceutical agent. Risk factors for toxicant-induced convulsions that may be discernible from a careful review of the patient's medical history include the following:

- Drug or alcohol (or both) withdrawal (e.g., benzodiazepine, meprobamate [which is rarely used], or barbiturate sedative-hypnotics) and drug overdose, with the paradoxical inclusion of some anticonvulsants (e.g., phenytoin, carbamazepine)
- Advanced age or demonstrated reduction in renal clearance (e.g., penicillins, cephalosporins [38], normeperidine [81, 87])
- Impaired drug metabolism (e.g., isoniazid and slow acetylator status)
- Drug-drug interaction (e.g., fluoroquinolone antibiotics, cyclosporine, and theophylline [88, 89])
- Preexisting or underlying seizure disorder
- Intrathecal, intraventricular, or intravenous route of administration (e.g., penicillin and other antibiotics, bethanechol) [24, 38, 90]

Bedside Evaluation

The bedside evaluation of a patient at risk for onset or recurrence of toxicant-induced convulsions and associated complications should focus on the presence of other signs that may provide clues to the nature of the toxic exposure, such as tricyclic antidepressant-induced electrocardiographic abnormalities or organophosphate-induced cholinergic manifestations. The clinical approach should emphasize continued close monitoring for evidence of seizure activity (e.g., signs of adrenergic excess, including pupillary dilation, hypertension, and tachycardia) and should

anticipate the development of complications of prolonged seizure activity, such as hypoxemia, respiratory failure, hyperthermia, hypoglycemia, and rhabdomyolysis.

Laboratory Evaluation

Appropriate laboratory evaluation includes routine monitoring of arterial blood gases, bearing in mind that arterial pH may be lower than 7.0 if measured during or immediately after a seizure episode. Other indicated studies include serum chemistries, with particular attention to bicarbonate, anion gap, glucose, sodium, calcium, and magnesium, and toxicological analysis of urine or blood or both, particularly in instances in which the results support clinical decision making and treatment (e.g., in theophylline or tricyclic antidepressant poisoning) or are of forensic importance. The rapid urine drug immunoassays that commonly are employed in clinical treatment settings are severely limited in some cases by their low sensitivity or specificity or both. Rapid tricyclic antidepressant “screens” that have been commercially available have been notably false positive for a variety of other drugs, such as phenothiazines, diphenhydramine, carbamazepine, orphenadrine, and cyclobenzaprine, and have failed to detect the presence of other cyclic antidepressant drugs, such as amoxapine [91].

Transient pleocytosis is a common, nonspecific finding in the cerebrospinal fluid obtained during the early postictal interval, with total cerebrospinal fluid white blood counts ranging from 1/ μ L to 50/ μ L in about 15% of patients after seizure episodes [25, 92]. It has been suggested that serum prolactin and adrenocorticotrophic hormone levels, which have been observed to increase and stay elevated for 10–20 min after generalized seizures [21], may help to differentiate seizure from pseudoseizure. These elevations also are recognized to be unreliable markers of seizure activity, however, because their specificity frequently is low in critically ill patients with multiple confounding disorders, and their sensitivity declines with increasing seizure frequency [2].

Electroencephalogram

The most valuable test employed during the diagnostic evaluation and management of patients with documented or suspected toxicant-induced convulsions is EEG.

The interpretation of EEG data should be made by a neurologist with an expertise in drug-induced EEG changes. This is particularly true for substances that can cause unusual EEG changes mimicking epilepsy. Toxic encephalopathy with epileptic-like changes (spikes, periodic shape waves) has been demonstrated with baclofen and 4-aminopyridine. On the other hand, electroencephalographic recordings made in patients receiving stable doses of bupropion showed that 19.8% of the population had abnormal, asymptomatic EEG findings. The incidence of sharp waves was significantly increased in women [93].

A role for continuous, rather than intermittent, EEG monitoring is supported by continued uncertainty as to the “extent to which occasional seizures produce incremental neuronal damage in refractory SE” [2]. This role is underscored further by observations that CNS injury can occur as a consequence of subclinical seizure activity within minutes of its onset and is supported by the argument that continuous EEG enhances the sensitivity and specificity of clinical seizure monitoring. Continuous EEG monitoring is especially applicable in instances in which the use of sedative-hypnotic agents or neuromuscular blockade blunts or abolishes the clinical seizure activity. Alternatively, the nonconvulsant (e.g., choreiform) effects of certain agents (e.g., cocaine) or manifestations of hypoxic-ischemic brain injury (e.g., decerebrate posturing) may be misinterpreted as seizures [2].

Further appreciation of the role of EEG in critically ill patients is based on the observation that as documented electrical seizure activity becomes recurrent or prolonged, the clinical manifestations become more subtle (e.g., facial twitching, clonic ocular movements) or may be clinically indistinguishable from coma of nonictal origin [74]. In a study of patient transfers to a neurological intensive care unit with a transfer diagnosis of SE, only 14 of 26 (54%) patients

satisfied the electrical definition for SE; of the remaining 12 patients, half were determined to be in drug-induced coma or were encephalopathic, and the other half were determined to have pseudoseizures [94].

EEG monitoring should be instituted for any patient who is managed with relatively long-acting neuromuscular blockade, who does not regain consciousness after initial anticonvulsant treatment, or who requires prolonged treatment for refractory status [74]. SE may be defined and recognized readily on EEG as “continuous spike, sharp wave, or sharp and slow wave discharges with a generalized distribution persisting for all or most of a tracing lasting 20 min or longer” [12]. Many electrographic patterns of seizure activity can occur, however, depending on the specific cause, neuroanatomy, and physiology involved, warranting formal interpretation by a qualified expert in most, if not all, instances [25]. Magnetic resonance imaging signal abnormalities in the hippocampus have been associated with SE [25]; however, the diagnostic utility of this and other imaging modalities in the evaluation and management of toxicant-induced convulsions has not been established.

Electrocardiogram

An electrocardiogram should be obtained in any patient presenting with isolated seizures or status epilepticus. Many drugs causing seizures are also cardiotoxic. The main electrocardiographic findings suggesting toxin-induced seizures are a widening of the QRS complex induced by a drug influencing the sodium channel and a prolongation of the QT interval by an agent inhibiting the outward potassium rectifier current.

Differential Diagnosis

The differential diagnosis of seizure-like activity that fails to fulfill the clinical and electrical definition of true seizure episode includes decorticate/decerebrate posturing, choreiform or athetoid movements, acute dystonic posturing, increased motor tone associated with hyperserotonergic states, pseudoseizure, posthypoxic myoclonus

[4, 94], syncope, migraine, drop attacks, panic attacks, cataplexy, and hysterical pseudoseizures [25]. Nontoxic etiologies of convulsive episodes that meet accepted case definition for true seizure activity commonly are divided into two clinical subgroups on the basis of whether the seizure activity or associated neurologic deficits they cause are predominantly focal or nonfocal.

Key Points in the Evaluation of Toxin-Induced Seizures

1. Suppression of clinical and electrical seizure activity is the main goal of therapy.
2. Phenytoin has no rational role in the treatment of toxicant-induced seizures (possible exceptions are aminopyridine antimuscarinic drugs).
3. Benzodiazepine and barbiturate anticonvulsant drugs are the mainstays of pharmacologic treatment in patients with toxicant-induced convulsive disorders.
4. Intravenous pyridoxine is the preferred first-line treatment for isoniazid-induced neurotoxicity; it should be administered on a gram-for-gram basis if the toxicant dose is known or in 5-g incremental bolus doses if isoniazid dose is unknown.
5. Administration of high-dose phenobarbital, higher-potency barbiturates (e.g., pentobarbital), midazolam, or propofol may be effective in the management of toxicant-induced convulsions that are refractory to first-line and second-line anticonvulsant pharmacotherapy.

Treatment

As generally applies to the management of ongoing or recurrent seizures of nontoxic origin, termination and suppression of further seizure activity are paramount in the management of a patient with toxicant-induced convulsions. Stopping seizure activity may play an integral role in

stabilizing the airway, ventilation, and circulatory status of the affected individual. In addition, *delay in termination of SE is associated with a marked decline in responsiveness to subsequent anticonvulsant treatment*. Lowenstein and Alldredge [74] observed an 80% response rate to first-line anticonvulsant treatment if it was initiated within 30 min of seizure onset and a decrease in response rate to less than 40% if treatment was begun 2 or more hours after onset of seizures.

The principal desired characteristics of an anticonvulsant regimen designed for use in a critical care setting are initial rapid onset of effect, subsequent prolonged duration of effect, marked enhancement in efficacy for instances when seizures prove refractory to initial treatment, and acceptably low acute and chronic adverse effect rates. Although some anticonvulsant drugs (e.g., phenytoin, fosphenytoin) are recommended widely for use in the general management of SE [2, 7, 25, 74], other choices may be more rational in the management of toxicant-induced convulsions, as discussed subsequently.

Initial Anticonvulsant Therapy

The ultimate goal of acute anticonvulsant drug treatment in the critical care setting is suppression of clinical and electrographic seizure activity or induction of a burst-suppression pattern on EEG, whichever occurs first [74]. Long-term anticonvulsant maintenance therapy usually is not indicated in patients in whom the sole cause of seizure activity is a transient metabolic or toxic disturbance (i.e., in the absence of a preexisting CNS structural disorder or seizure focus and without the development of a new and more permanent focus for recurrence) [7].

Management of seizures involves provision of supportive care and administration of an anticonvulsant to terminate the seizure promptly.

First-Line Therapy

Benzodiazepines are recommended as first-line therapy. Evidence for this is mainly from

nonpoisoned patients, as there are no randomized controlled trials or large case series that have investigated the effectiveness of benzodiazepines in poisoned patients. The level of evidence should be categorized as II-2. The choice of the benzodiazepine (diazepam, midazolam, or lorazepam) usually relies upon the physician's experience or local hospital policy on first-line benzodiazepine for seizures.

Benzodiazepines, such as diazepam and lorazepam, bind to the benzodiazepine receptor on the GABA_A chloride ionophore to increase the binding affinity of GABA to its receptor and to increase the frequency of Cl⁻ channel opening in response to GABA binding (Fig. 5). In addition, there is evidence that diazepam inhibits adenosine reuptake [96, 97], enhancing adenosinergic inhibition of excitatory neurotransmitter (e.g., glutamate) release. Lorazepam and diazepam exhibit a similar clinical response time (i.e., time to cessation of seizure activity); however, lorazepam has been shown to have a longer duration of anticonvulsant effect (12–24 h vs. 15–30 min) and is the preferred initial drug choice in SE management according to some authorities [7]. The successful use of lorazepam in the treatment of seizures, myoclonus, and other neurologic manifestations of serotonin syndrome is discussed in ► Chap. 24, “Serotonin Syndrome” and elsewhere [98]. Based on other, more toxicant-specific information sources, diazepam is the initial treatment of choice for convulsions caused by nerve agents (e.g., soman) [53, 99], hydroxychloroquine [100], or chloroquine overdose [101]. This recommendation simply may reflect the lack of experience to date with lorazepam treatment of these particular toxins.

The initial dosing for benzodiazepines is given in Table 4 [102]. Intravenous administration of antiepileptic drugs should always be the preferred route of treatment. However, depending on the treatment setting (i.e., prehospital emergency department or intensive care unit), alternative routes of administration may be considered. In the pediatric population, diazepam may be administered intrarectally (IR) in the available gel form.

Fig. 5 The GABAergic synapse as a target of anticonvulsant drugs. GABA is synthesized from glutamate in the presynaptic terminal and is packed into small synaptic vesicles. After release, GABA activates postsynaptic ion channels (GABA_AR, marked “1”) which mediate the chloride influx and thereby the inhibition of the postsynaptic cell. From the synaptic cleft, GABA is removed into the presynaptic terminal and into an adjacent glial cells by GABA uptake (“2”). A fraction of the transmitter is

degraded into succinic semialdehyde by GABA transaminase (“3”), which is present in the glial cells as well as in neurons. Pre- and postsynaptic metabotropic GABA_BR are indicated by ellipsoid bodies in the cell membrane but are no major target for anticonvulsants presently in use. GABAergic drugs against epilepsy act as positive modulators of the GABA_AR (“1”), blockers of the GABA uptake (“2”) or inhibitors of GABA degradation (“3”) (From Offermanns and Rosenthal [95])

Table 4 Intermittent drug dosing for status epilepticus

Drug	Initial dosing	Administration rates and alternative dosing recommendations	Serious adverse effects
Diazepam	0.15 mg/kg IV up to 10 mg per dose, may repeat in 5 min Peds: 2–5 years, 0.5 mg/kg (IR); 6–11 years, 0.3 mg/kg (IR); greater than 12 years, 0.2 mg/kg (IR)	Up to 5 mg/min IV pump	Hypotension Respiratory depression
Lorazepam	0.1 mg/kg IV up to 4 mg per dose, may repeat in 5–10 min	Up to 2 mg/min IV pump	Hypotension Respiratory depression
Midazolam	0.2 mg/kg IM up to maximum of 10 mg, max 0.2 mg/kg IV	Peds: 10 mg IM (>40 kg); 5 mg IM (13–40 kg); 0.2 mg/kg (intranasal); 0.5 mg/kg (buccal)	Respiratory depression Hypotension
Phenytoin	20 mg/kg IV, may give an additional 5–10 mg/kg	Up to 50 mg/min IV, may give additional dose 10 min after loading infusion	Arrhythmias Hypotension
Phenobarbital	20 mg/kg IV, may give an additional 5–10 mg/kg	50–100 mg/min IV, may give additional dose 10 min after loading infusion	Hypotension Respiratory depression
Valproate sodium	20–40 mg/kg IV, may give an additional 20 mg/kg	3–6 mg/kg/min, may give additional dose 10 min after loading infusion Peds: 1.5–3 mg/kg/min	Hyperammonemia Hepatotoxicity Thrombocytopenia

Adapted from Brophy et al. [102]. IV intravenous, IR intrarectal, IM intramuscular

Intramuscular (IM) midazolam or lorazepam is also an alternative to intravenous diazepam or lorazepam. On the basis of the published case experience and at least one prospective randomized study (performed, however, in a nonpoisoned pediatric population), termination of seizure activity (within 1–10 min) was observed after IM midazolam (0.2 mg/kg, max 7 mg) and compared favorably with treatment with intravenous diazepam (0.3 mg/kg, max 10 mg) [103].

Second-Line Therapy

There is no high-quality clinical trial evidence with which to select a second-line treatment for toxicological seizures unresponsive to benzodiazepines and evolving to SE. When benzodiazepines have failed, the debate concerns the choice between barbiturates or other anticonvulsants as second-line agents. In a systematic review of the evidence concerning the choice of phenytoin or barbiturates as second-line therapy for toxicological seizures, Shah et al. were not able to find any RCT comparing both drugs [104]. Experimental data suggest that phenytoin is unlikely to be effective or may be proconvulsant in some instances. Phenobarbital or thiopentone is probably a better option, but scientific evidence is based only on a few experimental data with a limited number of toxins and a limited number of case reports.

Although phenytoin and its phosphoester congener fosphenytoin may be appropriate choices for the treatment of patients with idiopathic seizure disorders or patients with defined structural or electrical foci of seizure activity, they are not rational choices of therapy for toxicant-induced convulsions, which result from a diffuse lowering of neuronal seizure threshold, rather than a spread of electrical activity from a focal origin. Phenytoin frequently is recommended as a second-line and maintenance anticonvulsant in the treatment of SE of nontoxicant origin [7, 10, 25, 74]. Phenytoin-induced blockade of voltage-dependent sodium channels inhibits the propagation of seizure activity from active electrical foci but has limited ability to elevate the threshold for seizures induced by GABA-antagonistic or glycine-antagonistic convulsant drugs (e.g., strychnine, picrotoxin, pentylenetetrazol) [105, 106].

Although it may be effective at preventing the spread of abnormal electrical activity from a CNS focus, phenytoin would not be expected to suppress the characteristically diffuse lowering of seizure threshold or oppose the increase in neuronal excitability induced by proconvulsant drugs, chemicals, and toxins.

A considerable body of experimental evidence exists indicating phenytoin's lack of anticonvulsant efficacy in the suppression of seizures induced by a variety of proconvulsant substances, including penicillin [107–109], pilocarpine [110, 111], cocaine [112], pyrethroids (e.g., deltamethrin, permethrin) [113], local anesthetics (e.g., procaine, lidocaine) [114, 115], theophylline [116–118], pentylenetetrazol [119], picrotoxin [119], strychnine [119], NMDA [26], and organophosphate insecticides [53]. There is evidence in animals that administration of phenytoin may enhance the proconvulsant potency of theophylline [117]. Phenytoin use in experimental animals has been reported to increase mortality rate in cyclic antidepressant toxicity [120]. One exception to phenytoin's apparent lack of anticonvulsant efficacy in toxicant-induced convulsions seems to be 4-aminopyridine-induced seizures, wherein anecdotal clinical and experimental animal evidence suggests phenytoin is efficacious [63, 64]. The mechanism of 4-aminopyridine-induced neurotoxicity is not precisely known, but seems to be related to the blockade of potassium channel. There also are ample clinical data to support the lack of efficacy of phenytoin in the treatment of alcohol withdrawal seizures [121–123].

The clinical evidence available to support recommendations regarding the use of phenytoin in the management of toxicant-induced convulsions is far more limited. The Veterans Administration (VA) Status Epilepticus Cooperative Study Group compared the initial anticonvulsant efficacy of intravenous lorazepam, phenobarbital, phenytoin, and diazepam followed by phenytoin after treatments were assigned randomly to patients with generalized convulsive SE [10]. In this study, the definition of treatment success was cessation of clinical and electrical evidence of seizure activity within 20 min of the start of infusion, with no

further seizure occurrence during the first hour after initiation of treatment. The 43.6% success rate for patients treated first with phenytoin was the lowest of any of the treatment groups and was significantly lower than that for lorazepam, 64.9% ($p < 0.001$). The significant difference between the lorazepam and phenytoin groups in the length of time required to complete drug infusion (mean infusion times – lorazepam, 4.7 min; phenytoin 33 min) might explain the observed overall difference in efficacy. Phenobarbital, which was infused over a mean interval of 16.6 min, was as effective as lorazepam, however, in patients with overt generalized convulsive SE, suggesting an alternative explanation (i.e., other than difference in infusion time) for the observed differences in treatment success.

Although the VA Cooperative Study included a group of patients whose episodes of SE were deemed to have resulted from the “toxic effects of therapeutic or recreational drug” exposure, the relevance of the study’s conclusions to the current discussion is limited by the absence of comparisons made among the various treatments in this toxicologic substratum of patients. Given the small size of this group ($n = 31$), it is unlikely that meaningful comparisons could be made among its treatment subgroups.

In general, medications that cause neuronal hyperpolarization via increases in chloride influx (or potassium efflux) and that increase neuroinhibitory tone or reduce neuroexcitatory tone (or both) by suppressing NMDA-glutamate sodium and calcium influx are, in theory, rational choices of therapy for toxicant-induced convulsions. Consistent with this rationale and supported by previously cited clinical trial data [10], widely accepted anticonvulsant regimens for the general treatment of SE begin with parenteral benzodiazepines (diazepam or lorazepam or both) [2, 7, 74]. Phenobarbital, frequently a third-line agent in the broader treatment of SE, is a more appropriate second-line choice than phenytoin for toxicant-induced recurrent seizures or SE. This assertion is based on previously stated arguments against the use of phenytoin in toxicant-induced convulsions and on the rationale that barbiturates are more likely than phenytoin to act in an

additive or synergistic manner with other GABA agonists, such as diazepam and lorazepam, to suppress toxicant-induced diffuse increases in neuronal electrical excitability.

Adverse acute effects of intravenous benzodiazepines include hypoventilation, depressed sensorium, and hypotension. With prolonged continuous infusion of propylene glycol-containing formulations of some drugs, such as diazepam (45% propylene glycol by volume) or lorazepam (80% propylene glycol by volume), coma, hyperosmolality, anion gap metabolic acidosis, and hyperlactatemia may occur [124–126]. This is a possible reason to prefer intravenous midazolam. Barbiturates also bind to the GABA_A complex, enhancing the binding of GABA and increasing the duration of Cl[−] channel opening and Cl[−] influx [35]. At high concentrations, some barbiturates directly open the Cl[−] channel and exert a direct agonist action on chloride influx and neuronal hyperpolarization. Experimental evidence supports the superiority of phenobarbital over phenytoin in preventing theophylline-induced seizures and death [117, 118]. Recommended dosing for phenobarbital as a second-line anticonvulsant after diazepam or lorazepam is 20 mg/kg intravenously infused at a rate of 50–100 mg/min. The time required for safe administration of an intravenous loading dose of phenobarbital, roughly 20–30 min in a 70-kg individual, is potentially a disadvantage compared with other agents (e.g., benzodiazepines or other barbiturates, such as thiopentone or pentobarbital) in the initial treatment of sustained convulsive activity. As Treiman and colleagues [10] observed, however, there was no significant difference in the initial anticonvulsant success rate between phenobarbital-treated and lorazepam-treated patients with SE in their study. There also may be prophylactic anticonvulsant and other favorable (e.g., sedative) effects from administering phenobarbital to highly seizure-prone individuals, such as individuals who present with moderately severe theophylline toxicity (e.g., with agitation, tremor, tachycardia) [127]. Potential acute adverse effects of therapy with parenteral phenobarbital and other barbiturates, especially the higher-potency agents, such as

thiopentone and pentobarbital, include CNS and respiratory depression and hypotension. Because of the possibility of hypotension and respiratory depression with a full loading dose in barbiturate-naïve patients, a common, yet untested regimen, is to give an initial phenobarbital dose of 400 mg in adults and repeat as necessary.

Special Conditions

From a pathophysiological and therapeutic standpoint, isoniazid-induced convulsions represent a unique subset of toxicant-induced seizures. The underlying proconvulsant mechanism of isoniazid involves inhibition of GABA synthesis and decline in presynaptic and synaptic GABA. Anticonvulsant drugs that work via indirect GABA agonism and require the presence of GABA to exert an effect on GABA_A chloride channel conductance are relatively ineffective in situations of synaptic GABA deficiency. Administration of pyridoxine, an essential cofactor in GABA synthesis, effectively restores GABA synthesis to adequate levels and promotes a return toward normal GABAergic neuroinhibitory tone [38]. Pyridoxine hydrochloride should be administered intravenously for acute isoniazid-induced neurotoxicity and given in gram-for-gram amounts if the toxicant dose is known or in 5-g incremental bolus doses if isoniazid dose is unknown (level of evidence II-3). The experimental demonstration of synergism between diazepam and pyridoxine in the treatment of acute isoniazid toxicity in dogs and rats [128, 129] provides support for the administration of indirect GABA agonists such as diazepam along with pyridoxine to patients with isoniazid-induced convulsions. This combination may be particularly beneficial if the amount of pyridoxine available for use in the emergent treatment setting is limited (see ► Chap. 65, “Isoniazid and Related Hydrazines”).

Pharmacological antagonists, such as naloxone and flumazenil, employed in the emergent reversal of toxic effects of CNS-depressant agents, such as opiate μ -receptor and benzodiazepine receptor agonists, may oppose but more often enhance the proconvulsant risks associated with administration and withdrawal of these drugs [130]. Although naloxone, based on experimental evidence, may antagonize the convulsant effects of propoxyphene

[131, 132], it also has been observed to potentiate the proconvulsant effects of meperidine's major oxidative metabolite, normeperidine [133], and of pentazocine [134] and should be used with caution in these settings. It has been well substantiated by clinical experience that the use of flumazenil (see ► Chap. 148, “Flumazenil”) should be avoided in patients at risk for acute benzodiazepine antagonist-induced withdrawal or in whom the presence of benzodiazepine agonist effects may protect against the proconvulsant effects of other drugs (e.g., tricyclic antidepressants) [135]. Although some clinical studies suggest that flumazenil can be administered safely empirically in unclear cases of multiple drug poisoning [136, 137], the conclusions reached by other investigators about the relative safety of this approach are limited by the confounding and neuroprotective presence of other anticonvulsant agents (e.g., phenobarbital) [138].

The use of propofol, levetiracetam, or lacosamide in the treatment of toxicant-induced seizures and SE is discussed below.

Treatment of Refractory Status Epilepticus

In addition to prompting questions as to the underlying etiology and appropriate selection of first-line treatment, prolonged or recurrent seizure activity may warrant increases in the potency, duration, and attendant risks of anticonvulsant therapy. This approach may require further provision of aggressive supportive measures before and during treatment (e.g., neuromuscular blockade, intubation, mechanical ventilation, external cooling, intravenous vasopressor therapy). Supportive care should include, when indicated, supplemental thiamine (100 mg IV three times a day), if there is any reasonable risk of deficiency; intravenous dextrose, if objective evidence (e.g., rapid blood assay) or suspicion of hypoglycemia supports the need; intravenous bicarbonate for correction of severe metabolic acidosis; and maintenance of brisk urinary output, with urine pH greater than 6.5, in an effort to prevent myoglobinuric renal tubular injury.

Table 5 Dosing for refractory status epilepticus

Drug	Initial dosing	Continuous infusion dosing recommendations	Serious adverse effects
Midazolam	0.2 mg/kg; administer at an infusion rate of 2 mg/min	0.05–2 mg/kg/h CI Breakthrough SE: 0.1–0.2 mg/kg bolus, increase CI rate by 0.05–0.1 mg/kg/h every 3–4 h	Respiratory depression Hypotension
Pentobarbital	5–15 mg/kg, may give additional 5–10 mg/kg; administer at an infusion rate of <50 mg/min	0.5–5 mg/kg/h CI Breakthrough SE: 5 mg/kg bolus, increase CI rate to 0.5–1 mg/kg/h every 12 h	Hypotension Respiratory depression Cardiac depression
Propofol	Start at 20 mcg/kg/min, with 1–2 mg/kg loading dose	30–200 mcg/kg/min CI Use caution when administering high doses (>80 mcg/kg/min) for extended periods of time (>48 h) Contraindicated in young children Breakthrough SE: increase CI rate by 5–10 mcg/kg/min every 5 min or 1 mg/kg bolus plus CI titration	Hypotension Respiratory depression Propofol infusion syndrome (cardiac and renal failure, rhabdomyolysis, metabolic acidosis)
Thiopentone	2–7 mg/kg; administer at an infusion rate <50 mg/min	0.5–5 mg/kg/h CI Breakthrough SE: 1–2 mg/kg bolus, increase CI rate by 0.5–1 mg/kg/h every 12 h	Hypotension Respiratory depression Cardiac depression

Adapted from Brophy et al. [102]. *SE* status epilepticus, *CI* continuous infusion

The global level of evidence for the pharmacological management of refractory status epilepticus is II-3 to III. Suggested dosing for refractory status epilepticus is illustrated in Table 5. A first recommended approach to refractory SE is the addition of midazolam, a potent, short-acting benzodiazepine, as an initial 0.2-mg/kg slow intravenous bolus followed by infusion at 0.75–10 µg/kg/min [74]. One of the advantages of this approach is that injectable formulations of midazolam do not contain propylene glycol and are not associated with propylene glycol toxicity during relatively prolonged infusion therapy.

As an alternative to phenobarbital, more potent barbiturates are frequently included in published regimens for refractory SE. Pentobarbital may be given at a recommended intravenous loading dose of 10–15 mg/kg administered over 1 h, followed by maintenance infusion at 0.5–1 mg/kg/h [74]. Thiopentone should be administered at a loading dose of 2–7 mg/kg (infusion rate < 50 mg/min), followed by maintenance infusion at 0.5–5 mg/kg/h.

The critical care provider should be prepared to institute pressor therapy, given the higher risk of

hemodynamic compromise with high-potency barbiturate anticonvulsants (see ► Chap. 46, “Barbiturates”).

Propofol is thought to act as a GABA agonist, with potent enhancement of chloride channel conductance in a manner that may be additive or synergistic with that of benzodiazepines or barbiturates [139]. A suggested propofol regimen for refractory SE that seems to be relatively widely endorsed by epileptologists consists of a 1–2-mg/kg loading dose, followed by infusion of 2–10 mg/kg/h [74]. The advantages of propofol and midazolam over other anticonvulsants include their rapid onset and short duration of action, allowing for prompt, continuous suppression of seizure activity during infusion and rapid assessment of neurologic status after discontinuation of treatment. Potential disadvantages of treatment with propofol include the associated high cost and elevated risks for hypertriglyceridemia and neuroexcitatory events, such as dyskinesias and convulsive movements, the latter being reported more frequently at doses less than 3 mg/kg [139]. Supporting clinical data include a published report that showed that intravenous

propofol bolus and maintenance infusion halted seizure activity in a 30-year-old woman who, after amoxapine overdose, had developed SE refractory to conventional therapy [140].

Adverse effects such as hypotension and bradycardia may be associated less frequently with propofol than with barbiturate anesthetic agents. This suggestion is challenged, however, by the findings of one clinical investigation comparing propofol with high-dose pentobarbital in the treatment of refractory SE [141]. Efficacy with regard to seizure control was not significantly different when the propofol and pentobarbital groups were compared, although the mean time to propofol-induced EEG burst suppression, approximately 2.5 min, was significantly shorter than that for pentobarbital, approximately 2 h. There was no significant increase in the incidence of adverse clinical effects, including hypotension, pneumonia, or prolonged intubation, in patients who received propofol compared with patients who received high-dose barbiturate treatment. The small number of patients (eight patients in each group) enrolled in this study and the severe systemic illness and multiorgan failure observed in both treatment groups limit interpretation of the outcome and dose–response data obtained in this study [139].

There is an increasing interest for an earlier introduction of more recent anticonvulsants (levetiracetam, lacosamide) as soon as benzodiazepines have failed. Besides promising data regarding efficacy, the main advantage of these recent drugs would be the absence of serious adverse effects and of significant drug–drug interactions. However, no data are available from poisoned population. In nonpoisoned patients, the relative effectiveness of five antiepileptic drugs (lacosamide, levetiracetam, phenytoin, phenobarbital, valproate) in the treatment of benzodiazepine-resistant convulsive status epilepticus was recently discussed from a meta-analysis of published studies. A total of 27 papers were available for data extraction. From the included studies, there was only one randomized double-blinded trial comparing valproate and phenobarbital. The levels of evidence of the studies were as follows: level 4 ($n = 18$), level 4- ($n = 3$), level 2b ($n = 5$), and level 1b ($n = 1$). Despite

numerous limitations (number of studies, bias, heterogeneity, etc.), the authors found that the highest efficacy was attributed to valproate, levetiracetam, and phenobarbital [142].

Key Points in the Management of Toxin-Induced Seizures

1. The fundamental pathophysiology of toxicant-induced convulsions involves relatively diffuse changes in central nervous system neurotransmitter balance, favoring neuroexcitatory over neuroinhibitory tone.
2. Risk factors for toxicant-induced convulsions include patient age, drug overdose or withdrawal, parenteral route of exposure (e.g., antibiotics), underlying seizure disorder, and impaired drug clearance.
3. As seizure activity becomes more prolonged, the risks of neuronal injury and systemic complications increase, clinical manifestations become less pronounced, and responsiveness to anticonvulsant treatment tends to decline.
4. Common systemic complications of toxicant-induced seizures include respiratory failure, aspiration pneumonitis, hyperthermia, rhabdomyolysis, and metabolic acidosis.
5. Subclinical status epilepticus occurs in a high percentage (26%) of critically ill patients with altered sensorium. Continuous electroencephalogram monitoring is essential in the management of patients at high risk for this occurrence (e.g., patients receiving neuromuscular blockers).

Special Populations

Age-related differences in general SE-related incidence, features, treatment, and outcome have been discussed thoroughly in the medical literature

[75, 143–145]. There is little published information, however, regarding such differences among various age groups of patients with toxicant-induced convulsive disorders. Nevertheless, it is appropriate to approach the evaluation and management of pediatric and geriatric patients with relatively high suspicion that age-related differences in risk factors (e.g., impaired drug clearance) and dose–response thresholds may predispose individuals in these age groups to the development of toxicant-induced seizures and related complications. Examples of clinical settings in which seizure occurrence has been observed to be age dependent include narcotic withdrawal [146], par-enteral propylene glycol administration [147], and parenteral antibiotic treatment [38].

There is a paucity of data describing which drugs are most commonly responsible for drug-induced seizures in children. Data obtained from a prospectively collected cohort of poisoned patients over a 2-year period showed that among 11,977 poisoning cases, pediatric patients (age < 18 years) represented 25.1% of the cases [148]. From these 3005 pediatric patients, 142 (4.7%) presented with drug-induced seizures. Most of the cases (75%) occurred in patients aged 13–18 years, and 61% resulted from intentional ingestions. Like in adults, antidepressants are the most common agent class, with a majority of the cases involving bupropion as etiologic agent. Anticholinergics and antihistamines were the second most common cause. Among infants and toddlers, sympathomimetics including illicit drugs were the leading agents.

Recommendations for the treatment of toxicant-induced SE in pediatric patients, based on recommendations for general management of pediatric SE, are essentially the same as for adults [75, 144]. Alternatives to intravenous anticonvulsant administration that are particularly appropriate considerations in younger pediatric patients include the intrarectal, intraosseous, and intramuscular (midazolam) routes.

Management of a critically ill patient with cardiovascular disturbances requires the clinician to consider that a cardiac toxin may be involved. This chapter emphasizes recognition of cardiac arrhythmias, conduction abnormalities, and specific electrocardiogram (ECG) findings that might suggest the involvement of a cardiovascular toxin. First, relevant cardiac physiology and the toxic mechanisms pertinent to poisonings and overdose are reviewed. Next, we describe a clinical approach to the recognition and management of patients with rate and rhythm disturbances from cardiovascular toxins. Lastly, we discuss some specific cardiovascular toxins that show how autonomic disturbances, membrane-depressant effects, triggered rhythms, and systemic influences produce the protean manifestations of a patient with cardiac poisoning.

Cardiac Physiology

Understanding some basic principles of toxicity facilitates the management of critically poisoned patients with cardiovascular disturbances.

Myocardial Cell Physiology

Differing pharmacology of the three important transmembrane ion channels responsible for the cardiac cell action potential (AP) makes the myocardial cell unique with respect to therapeutic and

Fig. 1 The five phases of transmembrane ion flow during action potential of an automatic myocardial cell with spontaneous diastolic depolarization. *TP* threshold potential

toxic actions of drugs and toxins. The three channels are (1) fast sodium channels, (2) slow calcium channels, and (3) outward potassium channels.

The AP of the cardiac cell has five phases (Fig. 1) [1]. When a cardiac cell AP reaches its threshold potential, opening of fast sodium channels results in a spikelike upward deflection due to the rapid influx of sodium ions (phase 0). The brief, rapid repolarization of the AP (the notch seen in phase 1) occurs via the efflux of potassium ions (and minimal influx of chloride ions) into the cell. This repolarization is attenuated by the opening of slow (L-type) calcium channels, which, despite their designation (which refers to rates of inactivation), facilitate rapid calcium entry. Together, the influx of calcium, ongoing efflux of potassium, and late sodium currents balance the cell's transmembrane potential to create and maintain a plateau phase (phase 2). Delayed inactivation of L-type calcium channels, combined with sodium channel closure and the opening of outward potassium channels, result in a rapid return to baseline transmembrane potential (phase 3). After repolarization, additional intracellular sodium is pumped out in exchange for extracellular potassium using sodium-potassium adenosine triphosphatase (ATPase) pumps, and the resting membrane potential (phase 4) is maintained by the inwardly rectifying potassium current until another impulse arrives to depolarize the cell or the cell spontaneously depolarizes. During phase 4, some cardiac fibers allow sodium ions to enter into the cell, raising the resting membrane potential, also known as spontaneous

diastolic depolarization. When the membrane potential reaches threshold, the fast sodium channels open, and another AP is generated.

Role of Calcium Ions in Myocardial Cells

A discussion of regional electrophysiological differences in the heart adds to the understanding of cardiotoxic actions of the various drugs. First, conduction in the His-Purkinje system and the atrial and ventricular myocardium depends on *sodium* entry via the fast sodium channels during phase 0. In contrast, conduction through the sinoatrial (SA) and atrioventricular (AV) nodes depends on *calcium* entry via the slow calcium channels during phase 0 (Fig. 2) [2]. Calcium influx also initiates myocardial contraction during the plateau phase 2; this calcium entry allows excitation-contraction coupling, the mechanism by which the depolarization of an AP results in the mechanical process of myocardial contraction.

Regulation of Cardiac Function

The Frank-Starling mechanism – defined as an increase in stroke volume in response to increased end diastolic volume – is one of the major determinants of cardiac output. In addition, the autonomic nervous system (ANS) has a significant effect on cardiac output. In the ANS, impulses are transmitted from the brain via the

Fig. 2 Schematic demonstration of the typical action potential generated in the sinoatrial and atrioventricular nodes versus the conduction systems of the His-Purkinje and atrioventricular cells. Atrial depolarization on the electrocardiogram (ECG) results in the P wave. The impulse spreads to the atrioventricular node, where specialized cells delay the transmission to allow atrial contraction; the impulse then continues to the ventricles via the bundle of His and the Purkinje fibers. This delay results in the P-R interval on the ECG. The QRS complex represents conduction cell phases 0, 1, and 2 (ventricular depolarization); the T wave indicates phase 3 (ventricular repolarization). The QT interval represents phases 2 and 3 of the action potential

preganglionic fibers that synapse with the postganglionic fibers and subsequently innervate an end organ. Transmission of the impulse occurs primarily through the release of the neurotransmitters acetylcholine and norepinephrine (Fig. 3).

Sympathetic Nervous System

Sympathetic fibers innervate most parts of the heart and increase heart rate, the rate of AV nodal conduction, and myocardial contractility. Norepinephrine from postganglionic fibers interacts with the β_1 -adrenergic cardiac receptors to increase myocardial cell permeability to sodium and calcium, increasing excitability, conduction, and contractility [1, 3].

Parasympathetic Nervous System

In the heart, postganglionic parasympathetic fibers from the vagus nerve innervate the sinus and AV nodes, where they cause the local release

of acetylcholine. Vagal stimulation of muscarinic receptors in these nodes primarily decreases excitability of the atria and slows the conduction of impulse into the ventricles to a point where atrial arrest or complete blockade of transmission at the AV node is possible. Direct effects on myocardial contractility are modest [3].

Pathophysiology

Arrhythmogenesis caused by xenobiotics can be divided into three general mechanistic categories: (1) abnormal impulse initiation, (2) triggered rhythms, and (3) abnormal impulse conduction [4].

Abnormal Impulse Initiation

While all myocardial cells have the potential to generate an AP as outlined above, only specialized conduction cells exhibit automaticity, i.e., the ability to generate an AP without external stimulus. The sinus node is the normal pacemaker because it has the fastest intrinsic firing rate; signals are received from the SA node at a rate that suppresses the firing of other potential autonomic foci (overdrive suppression). The intrinsic firing rate depends on four factors: (1) the resting potential, (2) the refractory period, (3) the threshold potential, and (4) the slope of diastolic depolarization (Fig. 4). An alteration in any of these four factors can cause normal atrial and ventricular working myocardial cells, which do not manifest automaticity, to generate automatic impulses. When the firing rate of any part of the myocardium exceeds the SA node rate, a new site of pacing will result [4].

Triggered Rhythms

Afterdepolarizations (ADs), or positive deflections of the AP, can occur during phases 2 through 4 and can then result in the abnormal initiation of impulses; these abnormal impulses are called triggered rhythms. Two types of ADs are categorized

Fig. 3 The elements of the autonomic nervous system and its sites of cardiovascular action. The boxes list drugs or toxins that may influence the cardiovascular system through the autonomic nervous system at various sites.

*May cause reflex bradycardia. [†]Sensitizes myocardium to catecholamines. *N* nicotinic receptors, *M* muscarinic receptors, *ACh* acetylcholine, *NE* norepinephrine

based on their temporal relationship with the repolarization phase of the AP: (1) early ADs and (2) delayed ADs (Fig. 5) [4, 5].

Early ADs are the most common predecessors to triggered rhythms that result from poisoning. These result from outward potassium channel blockade (Fig. 5a). By preventing the efflux of potassium required for restoration of phase 4 resting potentials, this blockade causes a surplus of positive ions intracellularly, resulting in delayed

return of the AP to its baseline and upward oscillations in the AP above threshold. The ECG manifestation of an early AD is manifested on ECG as a prolonged QT interval. This finding can progress to ventricular tachycardia and torsade de pointes (TdP) [6], commonly thought to occur through the phenomenon of superimposition of an R wave on a T wave (referred to as the R-on-T phenomenon) [7, 8]. The amplitude of triggered rhythms associated with early ADs is inversely related to heart

Fig. 4 An image depicting pacemaker cell membrane potential. Numbers represent phases of depolarization: resting potential (4), rapid depolarization (0), and repolarization (3). The solid line represents normal pacemaker cell membrane depolarization as the membrane potential approaches and crosses the threshold potential (dashed

line). Factors increasing the slope (double line) or increasing the resting potential (dark dotted line) of the cell will result in enhanced automaticity (pale dotted line). Conversely, decreasing the slope or decreasing the resting potential results in depressed automaticity and slowed pacemaker rate

Fig. 5 (a) Cardiac action potential showing potassium flow blockade during phase 3 leading to membrane oscillations or early *afterdepolarizations*. Triggered activity occurs when oscillations reach threshold voltage. (b)

Delayed afterdepolarizations also result in triggered activity and dysrhythmias (i.e., premature ventricular contraction (PVC) and ventricular tachycardia) when they reach threshold voltage (From .Ref. [150])

rate; thus, bradycardia predisposes an individual to TdP and other ventricular arrhythmias, while tachycardia is protective [9].

Delayed ADs occur when repolarization of the AP is complete or nearly complete and can result in premature ventricular contractions (Fig. 5b) among other rhythms. Delayed ADs are observed in conditions of intracellular calcium overload. In poisonings, this overload is associated most commonly with digitalis toxicity or excess catecholamine states. Delayed ADs can also result in triggered activity and have been implicated in certain arrhythmias, especially digitalis-associated bigeminal and idioventricular rhythms [10]. In distinction to early ADs, the amplitude of triggered activity associated with delayed ADs increases with heart rate (see

Fig. 5b) [150]. It has been suggested that pacing-induced increase in heart rate may worsen digitalis toxicity in poisoned patients [11, 12]. Basic science studies on delayed ADs supports this hypothesis,⁷ although transvenous pacing for symptomatic bradycardia after accidental digoxin overdose was well tolerated in one retrospective series [13].

Abnormal Impulse Conduction

Under normal conditions, an impulse initiated in the sinus node travels down the conducting tissues into the ventricles [4]. If an impulse arrives at an area of refractoriness or conduction block (ischemia, scar, or toxin-induced), it may travel down an alternative conduction pathway. If the impulse returns to the area that initially was refractory

Fig. 6 *Reentry*: Schema of Purkinje fibers or ventricular muscle through which impulse transmission occurs. (a) Normal depolarization of a muscle segment. Impulses spread simultaneously down various conduction pathways to depolarize distal areas. Depolarization and repolarization proceed homogeneously. (b) Reentry. The hatched area represents a local area with depressed conduction, which might be produced by a membrane-depressant

drug or focal myocardial ischemia or necrosis. An impulse traveling antegradely in an area of depressed conduction is blocked (*dark horizontal lines*); impulses traveling in adjacent pathways can pass through the area of conduction delay, however, in retrograde fashion. If tissue proximal to the depressed area is already repolarized and is now excitable, restimulation (reentry) occurs (From Ref. [150])

but is now excitable, a reentry “circuit” results (Fig. 6). These reentry circuits are the most common source of clinically significant tachyarrhythmias in nonpoisoned patients. Many cardiotoxins, particularly inhibitors of fast sodium channels, cause nonuniform slowing of conduction and shortening of the refractory period – forming a milieu for unidirectional block and reentry [14].

Toxic Mechanisms of Arrhythmogenesis

A combination of membrane-depressant effects, autonomic disturbances, and systemic metabolic imbalances may occur during poisoning from cardiotoxins. Knowledge of various effects of drugs that contribute to arrhythmogenesis facilitates recognition and treatment of the manifestations of cardiotoxicity.

Membrane Depression

A toxin-induced block in conduction prevents the propagating impulse from exciting the tissue ahead

of it. The manifestations of a conduction block vary depending on the toxin and its site of action.

Sodium Channel Blockade

Inhibition of the fast sodium channels (Fig. 7 and Table 1) decreases the maximum rate of rise and amplitude of the AP in Purkinje fibers and in atrial and ventricular myocardial cells. As a result, more stimulus current is needed to propagate an impulse throughout the His-Purkinje system and myocardium. Clinically the ECG may reveal QRS prolongation and, rarely, AV block; other ECG features are listed in Table 1. Nonuniform drug-induced depression of conduction may result in unidirectional block and reentry in the conduction system, resulting in tachyarrhythmias [4, 14].

Slow Calcium Channel Blockade

In the pacemaker cells of the SA node and AV node, where the slow calcium channel is the primary ion channel controlling depolarization, inhibition of this channel results in a slowing or inability of the tissue to conduct a cardiac impulse (see Fig. 2) [2]. Calcium channel inhibition results in depression of the SA node discharge rate (negative chronotropy) and slowing of conduction through the AV node (negative dromotropy). The

Fig. 7 Cardiac action potential showing that, when sodium channels are blocked, the rate or rise of phase 0 is decreased corresponding to a widening of the QRS complex on the electrocardiogram (From Ref. [150])

ECG manifestations may include sinus bradycardia (delay at the SA node), a prolonged P-R interval (delay at the AV node), or both [15]. Excessive delay prolongs AV conduction to the point of second-degree or complete heart block. Assuming that there is only isolated slow calcium channel inhibition of the pacemaker cells in an otherwise healthy heart, complete block in the pacemaker tissues is associated with an escape rhythm arising from the distal conduction tissues (His bundle, Purkinje fibers) or ventricular fibers. Patients dependent on ventricular or other escape rhythms are particularly sensitive to type I antiarrhythmics (e.g., lidocaine); the sodium channel blockade affected by these drugs impairs phase 0 depolarization and may thus abolish the only existing rhythm and cause asystole [16]. The slow calcium channels also are responsible for excitation-contraction coupling in the ventricular fibers. Impeding calcium entry into these cells results in a progressive depression of myocardial contractility (decreased inotropy). Similarly, vascular smooth muscle cells rely on calcium entry into the cells for contraction, and calcium blockade results in vasodilation. Combined, decreased myocardial contractility and vasodilation can result in significant hypotension.

Table 1 Selected fast sodium channel inhibitors and their consequences

Drugs and toxins	Electrocardiogram findings
Antidepressants	Rightward deviation of QRS axis
Cyclic antidepressants	Prominent R wave in AVR
Serotonin-norepinephrine reuptake inhibitors (e.g., venlafaxine)	Prolonged QRS and interventricular conduction delay
Bupropion	Ventricular tachycardia
Antihistamines	Ventricular fibrillation
Antiarrhythmics	Ventricular bradycardia (severe poisoning)
Type Ia	Asystole
Quinidine, disopyramide, procainamide	
Type Ib

Outward Potassium Channel Blockade

The significance of potassium channel blockade in the creation of early ADs has been discussed in the previous section on triggered rhythms (see Fig. 5). Although our discussion focuses on drugs and toxins, various non-toxicologic conditions have been associated with triggered rhythms, including myocardial stretch, hypoxia, acidosis, hypothermia, hypokalemia, hypomagnesemia, and

Table 2 Selected causes of acquired long QT syndrome

Antiarrhythmic drugs
Type Ia (disopyramide, procainamide, quinidine)
Type III (sotalol, amiodarone)
Antibiotics
Antimalarials (chloroquine, halofantrine)
Macrolides (azithromycin, clarithromycin, erythromycin)
Pentamidine
Fluoroquinolones (levofloxacin, moxifloxacin)
Antiemetics (domperidone, ondansetron)
Cholinergic agonists
Cisapride, organophosphates
Histamine receptor antagonists
Terfenadine, astemizole
Illicits (cocaine)
Opioids (methadone)
Psychiatric drugs
Antidepressants (citalopram)
Antipsychotics (droperidol, haloperidol, ziprasidone)
Neuroleptics (thioridazine, mesoridazine, and other phenothiazines)
Plants and herbals
Aconitine, grapefruit juice, <i>Hyoscyamus reticulatus</i> , rhododendron
Toxins
Arsenic, fluoride
Metabolic conditions
Hypokalemia, hypomagnesemia, hypocalcemia

hypocalcemia (Table 2) [6]. The development of toxin-induced long QT and torsade de pointes is more likely in the presence of one of the above conditions or a genetic predisposition.

Sodium-Potassium ATPase Blockade

The energy-driven sodium-potassium ATPase pump maintains a high sodium and potassium concentration gradient across cell membranes by pumping sodium out of and potassium into the cell [17, 18]. Inhibition of this pump by cardiac glycosides (e.g., digitalis) raises intracellular sodium concentrations, which increases intracellular calcium concentrations via the gradient-dependent sodium-calcium pump (Fig. 8a) [18].

Fig. 8 (a) Purkinje cell's normal state: The Na⁺/K⁺-ATPase pump and the Na⁺/Ca⁺⁺ pump regulate the balance of cations, with excess Ca⁺⁺ sequestered in the sarcoplasmic reticulum (S.R.) (b) In the presence of cardiac glycosides (e.g., digoxin), the Na⁺/K⁺-ATPase is inhibited, and overaccumulation of Na⁺ within the cell reverses the activity of the Na⁺/Ca⁺⁺ pump, significantly increasing the amount of Ca⁺⁺ available with each depolarization. In digoxin overdose, these processes lead to increased internal charge, resulting in delayed afterdepolarizations. Inhibition of the Na⁺/K⁺-ATPase simultaneously results in extracellular hyperkalemia. (Adapted from Haddad LM, Shannon MW, Winchester JF, et al.: *Clinical Management of Poisoning and Drug Overdose*, 3rd ed. Philadelphia, 1998. WB Saunders Company.)

This increase in intracellular calcium concentration has been associated with delayed ADs (see “Triggered Rhythms” section above) and certain digitalis-induced tachyarrhythmias (Fig. 8b) [19]. Sodium-potassium pump blockade can also induce hyperkalemia due to loss of intracellular potassium to the extracellular environment. Evidence from animal studies suggests that potassium depletion results in modulation of sodium-potassium ATPase inhibition by digitalis, and persons with low serum potassium are more likely to develop digitalis-induced arrhythmias [10, 19]. See ► Chap. 38, “Digitalis Glycosides” for a further discussion of this topic.

Fig. 9 Schematic overview of Ca^{2+} homeostasis during myocardial contraction. The β -adrenergic receptor (β), when stimulated, increases adenylate cyclase activity (AC), leading to activation of kinases that phosphorylate the L-channel, increasing Ca^{2+} entry. Ryanodine is the receptor that couples plasmalemmal Ca^{2+} currents to the sarcoplasmic reticulum, allowing release of intracellular pools of Ca^{2+} .

Adrenergic Receptors

β -Receptors

Of the β -receptors, the β_1 -adrenoceptor is the predominant subtype involved in drug-related cardiac poisoning. β_1 -Adrenoceptor activation results in increased cyclic adenosine monophosphate (cAMP) synthesis, which initiates a cascade of events culminating in calcium entry into the myocardial cells and increased inotropic, chronotropic, and dromotropic effects (Fig. 9). Phosphodiesterase then hydrolyzes cAMP and terminates its activity. Poisonings from direct β -agonists, theophylline, and caffeine result in tachyarrhythmias and – in the context of significant overdose – hypotension. Although the caffeine in commercially available beverages rarely causes significant toxicity, higher doses of caffeine in over-the-counter stimulants and diet medications and recent availability of large quantities of anhydrous caffeine preparations on the Internet has resulted in severe adverse effects and fatalities [19, 20]. Sympathomimetic drugs (e.g., cocaine and amphetamines) increase release of or inhibit reuptake or degradation of catecholamines and cause diffuse activation of adrenoceptor. Typically, α_1 and β_1 effects predominate, resulting in hypertension and tachyarrhythmias (see Fig. 3). β_1 -Adrenoceptor blockade decreases cAMP and subsequently blunts chronotropic, dromotropic, and

inotropic effects of endogenous and exogenous catecholamines. Activation of β_2 -adrenoceptor on the peripheral vasculature causes vasodilation, whereas activation of cardiac β_2 -adrenoceptor increases ventricular contractility [21].

α -Adrenoceptor

In poisoning – e.g., imidazoline or yohimbine – clinically significant toxicity involves activation of the α_1 -adrenoceptor subtype in arterial vasculature and/or α_2 -adrenoceptor subtype activation in the brainstem. *α_1 -Adrenoceptor activation* results in elevated intracellular calcium levels and subsequent arterial constriction with a rise in blood pressure. *Central α_2 -adrenoceptor agonism* decreases cAMP levels and inhibits sympathetic output, increases parasympathetic output, and produces sedation (see Fig. 3). Notably, medications administered for one desired α -adrenergic effect can have severe effects on the opposing receptor type. In the case of the over-the-counter imidazolines tetrahydrozoline and oxymetazoline, the desired α_1 -mediated peripheral vasoconstriction obtained by topical application can become life-threatening with α_2 -mediated hypotension and bradycardia in supratherapeutic exposures [22]. α_1 -mediated agonist effects (notably, hypertension) can precede the α_2 effects (hypotension, bradycardia, and mental status depression); in the context of imidazoline poisoning in children, life-threatening

hypertension has been reported to precede hypotension [23]. α_1 -Antagonist activity results in decreased intracellular calcium with subsequent arteriolar relaxation and hypotension (see Fig. 3).

Cholinergic Receptors

Acetylcholinesterase is the enzyme responsible for degradation of acetylcholine. Toxins (e.g., organophosphates) that inhibit acetylcholinesterase result in elevated acetylcholine concentrations at muscarinic and nicotinic receptors. A variety of sympathetic and parasympathetic signs and symptoms may be present after toxicity. The cardiovascular effects of acetylcholinesterase inhibitors are mediated by actions both on nicotinic and muscarinic receptors.

Nicotinic Cholinergic Receptors

Shortly after exposure to acetylcholinesterase inhibition, cardiovascular toxicity results from agonist activity at the ganglionic nicotinic cholinergic receptor. Although these receptors are present on parasympathetic and sympathetic postganglionic fibers, sympathetically mediated effects (tachycardia and hypertension) predominate. With higher doses, parasympathetic stimulation and neuromuscular blockade are seen. These effects are seen after exposure to acetylcholinesterase inhibition, as well as in nicotine poisoning, the incidence of which – especially in pediatric patients – is expected to increase since the introduction of “e-cigarettes” to the consumer marketplace [24, 25].

Muscarinic Cholinergic Receptors

The delayed effects of acetylcholinesterase inhibition involve stimulation of muscarinic cholinergic receptors in myocardial tissue, which decrease SA node excitability and AV node conduction, resulting in sinus bradycardia and varying degrees of AV block (see Fig. 3). Inhibition of the cardiac muscarinic receptors – a phenomenon seen with exposure to antihistamines, tricyclic antidepressants, and other anticholinergic xenobiotics – prevents acetylcholine binding, reducing parasympathetic restraint of heart rate and resulting in unopposed sympathetic

stimulation. This stimulation causes a modest sinus tachycardia with heart rate generally less than 150 beats/min and a modest rise in blood pressure due to increased cardiac output (see Fig. 3).

Altered Central Autonomic Nervous System Activity

Many toxins suppress or enhance ANS activity through the central nervous system (CNS) and subsequently result in peripheral cardiovascular effects. Poisoning from clonidine, a central α_2 -agonist, often results in reduced CNS-mediated sympathetic activity and increased parasympathetic tone, causing a decrease in heart rate and hypotension. Conversely, many CNS stimulants (e.g., cocaine and amphetamines) cause an increase in CNS-mediated sympathetic tone, resulting in tachycardia and hypertension. In a healthy heart, sympathetic stimulation can increase cardiac output twofold to threefold.

Systemic Influences

Many critically poisoned patients have coexisting systemic factors that further influence and exacerbate cardiotoxicity. Hemodynamic changes resulting from hypovolemia, fever, electrolyte abnormalities, acidosis, and hypoxia also must be taken into consideration and corrected.

Clinical Manifestations of Toxic Effects: Cardiac Arrhythmias and Conduction Abnormalities

This section discusses the recognition of cardiac arrhythmias, conduction abnormalities, and specific ECG findings that might help the clinician narrow the differential diagnosis in an unknown overdose. Because most conduction abnormalities are accompanied by abnormalities in heart rate, our clinical approach to a patient begins with categorizing them as having bradycardia or tachycardia. Some toxins cause conduction disturbances without rate alteration and are considered separately.

Fig. 10 Algorithm for determining causes and management of bradycardia. *Toxins with potential for direct toxicity may manifest only mild signs early in the course of poisoning. [†]Agents also may cause tachyarrhythmias (see Table 4). [‡]If low systemic vascular resistance.

[§]Glucagon is particularly helpful for β -blocker poisoning.

[¶]If signs of membrane depression. Helpful in suspected calcium channel overdose; may be harmful in digoxin overdose

Bradycardia

As outlined in Fig. 10, our approach to the diagnosis and management of bradycardia begins by classifying the patient into two broad categories based on ECG findings and perfusion status. Similarly, we separate cardiodepressant drugs

into two categories based on whether they directly or indirectly influence cardiovascular function. Drugs that directly impair cardiac function do so through their effects on myocardial membranes and receptors (e.g., calcium channel blockers and β -blockers). Drugs that have indirect effects on the cardiovascular system

typically function by altering autonomic output or causing reflex changes in heart rate (e.g., γ -hydroxybutyrate or phenylpropanolamine). It is important to note that there is significant overlap between mechanistic classification with respect to response to therapeutic interventions and that some exposures (e.g., organophosphates) may require significant administration of either fluids or atropine prior to resolution of clinical effects.

Bradycardia with Conduction Abnormality or Hypoperfusion

Agents that directly inhibit conduction and decrease contractility generally present with more profound ECG abnormalities and cardiovascular instability than agents with indirect toxicity. Bradyarrhythmias and hypotension are the hallmark of these toxins. Mild sinus bradycardia may be the only ECG abnormality despite clinical findings of hypoperfusion. Hypotension in these cases is evidence for depressed contractility from a direct myocardial toxin or vasodilation as opposed to rate-related shock. High-degree heart block (Mobitz II or third-degree AV block), sinus arrest with AV junctional or ventricular escape rhythm, widening of QRS, prominent R wave in EKG lead AVR, and asystole also suggest the presence of a direct myocardial toxin. Some agents that cause bradyarrhythmias (e.g., type IA antiarrhythmics, cardiac glycosides) predispose the patient to ventricular tachyarrhythmias through reentry mechanism or delayed ADs, as discussed above.

Bradycardia Without Conduction Abnormalities or Hypoperfusion

Patients who present with sinus bradycardia with first-degree or Wenckebach AV block may be manifesting signs of early poisoning from a direct myocardial toxin. More often, however, these findings suggest drugs and toxins with indirect toxicity that results in less myocardial depression and hemodynamic instability than direct effects on the conduction system. Most indirectly acting cardiodepressants either decrease sympathetic tone or increase parasympathetic tone, typically with heart rates of 40–60

beats/min, without causing severe hypoperfusion (see Fig. 10). Higher grades of AV block are seen infrequently.

Treatment

The goal of management in a patient with symptomatic bradycardia from an unknown poisoning is to improve perfusion by increasing cardiac output and reversing vasodilation. Treatment should focus on increasing heart rate if rate-related hypotension is suspected and/or improving inotropy if myocardial contractility is impaired. Atropine and pacing should be initiated and generally are sufficient for indirectly acting cardiodepressants, but may be ineffective in management of bradycardia associated with direct toxins. Specific antidotes to individual direct toxins should be considered based on clinical response to certain interventions and additional clinical history. With severe intoxication, heart block or asystole sometimes is associated with an inability to generate an impulse even with high-voltage pacing [26].

If hypotension is present despite normal or increased heart rate or in association with high-grade AV block, the clinician should assume contractile dysfunction and initiate treatment with crystalloid fluids and an inotropic agent. Epinephrine, dopamine, norepinephrine, or vasopressin should be started and titrated to a dose that restores perfusion (Level of Evidence [LOE]: III). Individual reports have indicated that glucagon can increase rate and contractility in poisonings from β -blocker, calcium channel blocker, and severe tricyclic antidepressant (TCA) poisoning (LOE: III) [27]; although given its use of cAMP-mediated processes to circumvent blocked β -adrenergic receptors, its effects are likely most pronounced in the context of β -blocker toxicity [27]. Outside documented effects in animal models, support for the clinical use of glucagon in cardiovascular poisoning is not strong [28]; however, in the context of life-threatening β -blocker toxicity, its use may be of potential benefit (LOE: III). Isoproterenol also may be used for unresponsive sinus, junctional, or ventricular bradycardia (LOE: III). If the ECG reveals a wide QRS, sodium bicarbonate boluses may

reverse the effects of cardiotoxins on fast sodium channels (LOE: II-2) (see Table 1). If appropriate, toxin-specific therapy, such as calcium (for negative inotropic effects of calcium channel blockers) and digoxin antibodies, should be instituted. Two additional therapies – hyperinsulinemia-euglycemia therapy and lipid emulsion – are described below and in more detail in the chapters specifically devoted to these interventions. As noted above, concomitant electrolyte abnormalities, hypoxia, and acidosis should be corrected because they may contribute to failure of pacing stimulus to depolarize cardiac cells (LOE: III).

Tachycardia

Our analysis of tachyarrhythmias in poisoned patients begins by classifying them into a wide-complex versus a narrow-complex rhythm. This distinction serves two primary purposes. First, it allows the clinician to narrow the differential diagnosis to a group of toxins responsible for the arrhythmia (Table 3). Second, the clinician can use the classification scheme to decide on initial therapy concomitant with an attempt to establish the diagnosis.

Wide-Complex Tachycardia

Monomorphic tachycardia of uncertain origin, polymorphic ventricular tachycardia (PVT), and bidirectional ventricular tachycardia (VT) are three types of wide-complex tachycardia (WCT) that are encountered in poisoned patients. When the patient is hemodynamically stable, therapy varies for the three types of WCT. In this section, we progress through a discussion on how to identify subtypes of WCT; subsequently, we present treatment options for each of these subtypes. Figure 11 provides a modified advanced cardiac life support (ACLS) algorithm for managing a patient with a WCT secondary to poisoning.

Monomorphic Wide-Complex Tachycardia. When an ECG reveals a wide-complex QRS with a uniform morphology and a constant RR interval, two common entities should be considered: VT and supraventricular tachyarrhythmia (SVT) with intraventricular conduction delay.

Table 3 Differential diagnosis of drug-induced or toxin-induced tachyarrhythmias

Narrow-complex tachyarrhythmias
Anticholinergic
Amantadine
Antihistamines ^a
Atropine, belladonna, scopolamine
Cyclic antidepressants ^a
Mushrooms (muscarine-containing, e.g., <i>Clitocybe dealbata</i>)
Neuroleptics (thioridazine ^a and mesoridazine ^a also are membrane depressants)
Plants (e.g., Jimson weed)
Sympathomimetic
Amphetamines and their congeners (e.g., ecstasy)
Caffeine
Chloral hydrate ^a
Cocaine ^a
Ethanol
Ephedrine and pseudoephedrine
Lysergic acid diethylamide (LSD) and other hallucinogens
Monoamine oxidase inhibitors
Phencyclidine
Scorpion or spider envenomation
Sedative-hypnotic withdrawal
Selective serotonin reuptake inhibitors
Theophylline ^a
Cholinomimetic
Organophosphates
ECG
Sinus tachycardia
Supraventricular tachycardia (normal conduction)
Treatment
Specific therapies include antidotes depending on xenobiotic
Correct hypotension, hypoxia, or electrolyte abnormalities
Esmolol or other short-acting beta-blocker infusion for intractable tachycardia in the absence of hypotension or other signs of myocardial depression
Wide-complex tachyarrhythmias
Antiarrhythmics (type Ia, Ic, III) ^c
Antihistamines ^c
Arsenic ^c
Carbamazepine
Cardiac glycosides
Chloral hydrate
Cocaine (high doses)
Cyclic antidepressants
Sodium fluoride ^c

ECG electrocardiogram, *VF* ventricular fibrillation, *VT* ventricular tachycardia

^aAny supraventricular arrhythmia can deteriorate to a ventricular arrhythmia, but this occurs more frequently with these agents

^bContraindicated if suspicion of membrane-depressant drug overdose

^cAgents that can cause torsade de pointes and monomorphic VT

Although implementing the optimal therapy can be facilitated greatly if VT is distinguished from SVT using published guidelines [29], previous studies in the general population with WCT have shown that even experienced physicians have difficulty in differentiating VT from SVT [30]. Hemodynamic stability or instability cannot be used to determine between the two arrhythmias [31]. In poisoned patients with a monomorphic WCT, initially, it is safer to assume and treat as if the arrhythmia is VT (see later). When initial treatment measures have been instituted and the patient is hemodynamically stable, attempts to differentiate between VT and SVT may be considered. In hemodynamically stable patients, carotid sinus massage or other vagal maneuvers can be applied and may indicate a supraventricular arrhythmia when it abolishes the rhythm or slows the rate. Although certain key ECG features suggest VT (Table 4), these features have not been validated in poisoned patients. Adenosine may provide useful diagnostic information in patients

with WCT of uncertain origin [32]. Table 3 lists toxic causes of WCT, and the later section on specific toxins discusses those that are commonly encountered in poisoning.

Impaired conduction in the His-Purkinje system resulting in QRS widening greater than 100 ms and/or rightward deviation of the terminal 40-ms frontal plane QRS vector (130–270°) suggests significant cardiotoxicity and is predictive of seizures from TCA poisoning (see Figs. 12 and 13) [33, 34]. An important electrocardiographic manifestation of this rightward deviation is the terminal R' in AVR: a positive deflection measuring greater than 3 mm is a significant predictor of seizures or arrhythmias in TCA poisoning (Fig. 14) [35]. Although these ECG findings in poisoning most commonly suggest antihistamine or TCA involvement, similar intraventricular conduction delay is evident with other toxins that impede fast sodium channels (see Table 1) [36].

Treatment. Because many overdoses resulting in a WCT are due to fast sodium channel inhibition, an important modification to the ACLS treatment algorithm (as shown in Fig. 11) involves the contraindication of type Ia and Ic antiarrhythmics (e.g., procainamide) and the introduction of sodium bicarbonate bolus therapy. The clinical status should dictate the initial method of treatment for the WCT. When associated with hemodynamic compromise, cardiac ischemia, or cerebral insufficiency, immediate termination of the arrhythmia should be attempted with direct current cardioversion and intravenous sodium bicarbonate. Magnesium administered empirically may be beneficial. The patient who is clinically stable can be treated with sodium bicarbonate and antiarrhythmic therapy. Lidocaine has been the antiarrhythmic of choice in this setting, although amiodarone may replace lidocaine as more evidence becomes available (see discussion below). Sodium bicarbonate has emerged to be the first line of treatment for membrane depression from diphenhydramine, TCA, and poisoning from other agents with fast sodium channel blockade activity (see Table 1) [37] (LOE: II-2). Sodium bicarbonate is believed to be beneficial as a result of increasing extracellular sodium, increasing

Fig. 11 Algorithm for management of wide-complex tachycardia (WCT) of uncertain origin in poisoning and drug overdose. *Quinidine, procainamide, disopyramide, flecainide, and propafenone. †Unless contraindicated by pH greater than 7.55, cerebral edema, or severe hypokalemia. ‡Use for refractory ventricular arrhythmias, but may worsen hypotension in poisoned patients. §Strongly

recommend use of a cardiology consultant or esophageal lead confirmation of atrial rhythm before use of calcium channel blockers, β -blockers, or digitalis in WCT. ECG electrocardiogram, H & P history and physical examination, HR heart rate, NaHCO_3 sodium bicarbonate, SVT supraventricular tachycardia, v/s versus, VT ventricular tachycardia

extracellular pH, and lowering extracellular potassium, all of which attenuate the effects of TCA and other fast sodium channel blockers [38–41]. There are further discussions of this topic in the chapters on sodium channel blocking antiarrhythmics and on sodium bicarbonate.

When these initial stabilizing measures have been implemented, further attempts to

differentiate the cause of WCT should be undertaken so that toxin-specific therapy can be administered (e.g., digitalis antibodies for digitalis overdose). Calcium channel blockers and β -blockers are contraindicated in WCTs of uncertain etiology because their vasodilatory or myocardial-depressant effects may cause sudden cardiovascular collapse. If pharmacological therapy is unsuccessful, sustained WCT, especially with a rate greater than 150 beats/min, should be treated with electrical cardioversion.

ACLS guidelines from 2010 recommend procainamide, amiodarone, or sotalol for the treatment of stable WCT [42]. Other than in case reports and a case series, the use of amiodarone has not been studied in poisoned patients [43–45]. In a small case series in which 13 of 17 patients with aconite poisoning had ventricular tachyarrhythmias, amiodarone suppressed VT in the five patients in whom it was used [45]. Further reviews of the management of aconite poisoning have also revealed a potential role of flecainide [46]. Lidocaine was used in 11 patients and was

PVC, premature ventricular contraction

^aThese criteria have not been validated in ventricular tachycardia associated with poisoning

Fig. 12 Electrocardiogram (ECG) from a 53-year-old woman who ingested unknown quantities of a tricyclic antidepressant. The patient had a sustained wide-complex tachycardia with a normal blood pressure despite receiving multiple ampules of sodium bicarbonate boluses and a

lidocaine drip. After 17 h in this rhythm, sinus tachycardia returned spontaneously, and the patient fully recovered without any specific interventions. This ECG was interpreted as ventricular tachycardia by two separate cardiologists

Fig. 13 Electrocardiogram (ECG) from a 39-year-old man after a tricyclic antidepressant overdose. The ECG shows signs of impaired conduction in the His-Purkinje system: QRS widening greater than 100 ms and rightward

deviation of the terminal 40-ms frontal plane QRS vector (aVR). In the presence of tricyclic antidepressant overdose, these ECG findings suggest significant cardiotoxicity

Fig. 14 A positive deflection greater than 3 mm of the terminal portion of lead AVR (R'), frequently called a *terminal R*, is a significant predictor of seizures or arrhythmias in tricyclic antidepressant poisoning. Similar intraventricular conduction delay suggests presence of a fast sodium channel blocker in a poisoned patient

ineffective in all cases. Additional publications supporting the use of amiodarone are mainly limited to case reports, including a 17-year-old patient with cardiac arrest secondary to butane abuse [44], a 45-year-old patient with cardiac arrest after ingestion of 2 g of flecainide [47], and a 26-year-old with ventricular fibrillation after ingestion of 25 mg of digoxin [48]. Although these reports and some animal studies [49] have analyzed the use of amiodarone in WCT due to

poisoning, current evidence does not indicate whether amiodarone or lidocaine would be preferable in these cases. Outside of poisoning cases, multiple studies have shown that amiodarone is preferred over lidocaine for refractory, shock-resistant ventricular tachycardia (LOE III) [50, 51]; however, current data do not indicate survival benefit from administration of antiarrhythmic drugs in refractory or pulseless ventricular tachycardia. Amiodarone should be considered for recalcitrant arrhythmias. Hypotension and bradycardia are the major acute adverse effects from amiodarone and are related to the rate of infusion. These adverse effects should be taken into consideration before its use in poisoned patients.

Extracorporeal life support is a further treatment modality to be considered for intractable toxin-induced cardiac failure; its use has been described in a variety of case reports. Several treatment modalities are included under the term extracorporeal life support, including extracorporeal membrane oxygenation (ECMO, further subdivided into venoarterial and venovenous modalities), emergency cardiopulmonary bypass, and intra-aortic balloon pumps. Case reports of severe toxin-induced cardiovascular compromise

Fig. 15 Electrocardiogram (ECG) from a 63-year-old woman who had ingested unknown amounts of thioridazine. She presented with sinus bradycardia at a rate of 20–50 beats/min and hypotension requiring atropine and dopamine. Six hours after ingestion, she developed several episodes of torsade de pointes (TdP) shown in the lower panel, which was preceded by the strip in the upper panel.

(Note the presence of “warning signs” of TdP discussed in the text: giant U waves, bradycardia, extrasystoles, and pause-dependent enhancement of T-U wave). The patient was cardioverted and subsequently placed on an isoproterenol drip, and the ECG eventually became normal without any further episodes of TdP

describe treatment with venoarterial extracorporeal membrane oxygenation (VA-ECMO) – a modality that allows both pulmonary (oxygenation) and circulatory support – and intra-aortic balloon pumps. Cases in which these treatment modalities have been successful – including verapamil [52], flecainide [53], diltiazem [54], digoxin [55], propranolol, bupropion [56], and a variety of combined ingestions [57] – illustrate that VA-ECMO and intra-aortic balloon pumps show promise when other treatment modalities have failed.

Polymorphic Ventricular Tachycardia. With PVT, the ECG reveals a WCT with beat-to-beat variation in the QRS morphology and RR interval (Fig. 15). The pathophysiology of PVT, as discussed earlier, is different from monomorphic VT, and consequently therapeutic options differ. PVT often occurs in the setting of a prolonged QT_c interval, in which case it is referred to as TdP.

Agents that cause TdP typically lengthen repolarization as evidenced by prolongation of QT_c interval and appearance of U waves on the ECG (see Fig. 15). These U waves represent early ADs. Although QT_c greater than 500 ms after drug exposure places the patient at higher risk for TdP

(LOE III) [58], the arrhythmia can occur at shorter QT_c intervals as well [6]. These arrhythmias often are associated with and often precipitated by pauses due to sinus bradyarrhythmia or sinus arrest or a pause after a premature beat, because bradycardia enhances the ADs. Factors that are predictive of TdP in the setting of a prolonged QT_c interval are the presence of “warning signs,” such as giant U waves, ventricular bigeminy, pause-dependent lengthening or enhancement of T-U wave, extrasystoles, and bradyarrhythmias [6]. Ventricular bigeminy with prolonged QT_c interval has been called impending torsade [6]. The pathophysiology of TdP is discussed separately under section “[Triggered Rhythms](#)” above. A more detailed discussion of the pathophysiology of TdP can be found in the chapter on dysrhythmia. Of note, a QT nomogram has been developed that was shown in one study to accurately predict arrhythmogenic risk for drug-induced QT prolongation; this nomogram is shown in Fig. 16 [59].

Treatment. If TdP is sustained and causes hemodynamic compromise, it can be treated primarily with electrical cardioversion in conjunction with the administration of magnesium. In

Fig. 16 QT nomogram, courtesy of Dr. Geoffrey Isbister. QT Interval Nomogram. The QT interval should be measured manually from the beginning of the Q wave to the end of the T wave in 6 leads; the median QT interval is then calculated. The QT interval thus obtained is plotted against the patient's heart rate in the nomogram; if the resulting

point is above the line, the patient is considered at risk for torsade de pointes. Of note, the information obtained from this nomogram may not be applicable in certain circumstances due to age- and sex-based QTc variability (Image from Ref. [59])

general, treatment of TdP or prolonged QT_c with the abovementioned warning signs is directed at suppression of early AD and acceleration of heart rate. Most often, the arrhythmia is not sustained and terminates spontaneously. The challenge lies, however, in prevention of its recurrence. TdP should be treated initially with a rapid bolus of magnesium sulfate (2–5 g over 30–60 s), which decreases the amplitude of early AD and suppresses triggered rhythms (LOE III). Treatment with a slower infusion of 2 g over 2 min should be considered in the presence of the warning signs (especially bigeminy) with a prolonged QT_c on ECG [5, 60]. Recurrent warning signs or arrhythmias can be treated with a second bolus in 5–15 min and, if necessary, a maintenance infusion at 3–10 mg/min. Bradycardia is associated with a more pronounced AD, and because toxin-induced TdP is pause-dependent, increasing the heart rate generally suppresses the AD and the emergence of TdP. If magnesium sulfate is ineffective or bradyarrhythmias occur, an isoproterenol infusion or electrical pacing can be instituted to accelerate the heart rate or shorten the QT interval (LOE III); overdrive pacing has been shown to be effective in terminating the recurrence of QT prolongation in drug-induced and genetically

determined torsade de pointes (LOE III) [61, 62], apparently through increased repolarizing potassium currents and thus shortening QT intervals [63]. The β₁- and β₂-adrenoceptor agonist isoproterenol (1–4 μg/min) may be used to accelerate the heart rate; the infusion should be titrated to a rate of 90–110 beats/min [61]. As noted above, tachycardia usually abolishes or prevents emergence of TdP [9], at which point the pacing rate should be decreased to the lowest rate that abolishes ventricular ectopy (usually 80–100 beats/min). Hypokalemia can exacerbate TdP, and potassium supplementation, even in normokalemic patients with drug-induced prolonged QT_c, has been shown to normalize repolarization abnormalities (LOE III) [60, 64]. Serum potassium should be checked and maintained in the high-normal range (4.5 mEq/L) in patients at risk for TdP [64].

Bidirectional Ventricular Tachycardia. ECG findings reveal a tachycardia with a wide QRS morphology that usually is alternating in direction with a constant RR interval (Fig. 17). In rare arrhythmia, bidirectional VT is almost pathognomonic for digitalis toxicity and should be treated with digoxin-specific antibodies [65] although this rhythm has also been associated with ingestion of aconite (see below) [66, 67].

Fig. 17 Bidirectional ventricular tachycardia suggestive of digitalis toxicity

Narrow-Complex Tachycardia

Narrow-complex sinus tachycardia is probably the most common arrhythmia seen in poisoned patients. Sympathomimetic and anticholinergic drugs are common causes of supraventricular arrhythmias in poisoning, although other indirect influences – including fever, hypoxia, hypovolemia, and agitation – often contribute to toxicity. Toxin-induced SVTs generally resolve with supportive care. Some toxins that induce tachycardia also possess membrane-depressant properties with a potential to cause myocardial depression (Figs. 15 and 16). The clinician can risk stratify these patients by assessing the ECG for conduction abnormalities. The clinician should suspect digitalis toxicity in any patient with an atrial tachycardia and AV block (usually 2:1 AV block). Digitalis is well known to increase automaticity and cause AV nodal conduction blockade.

Treatment. Supportive therapy and cardiac monitoring usually are sufficient for a patient with narrow-complex tachycardia, because tachycardia frequently subsides when the offending agent is eliminated. Hypovolemia, hyperthermia, and hypoxia can exacerbate tachyarrhythmias in poisoned patients and should be corrected. Pharmacologic therapy or electrical cardioversion usually is reserved for SVTs or tachyarrhythmias associated with hemodynamic compromise, active myocardial ischemia, acute heart failure, or cerebrovascular insufficiency. When treatment is warranted for a narrow-complex supraventricular arrhythmia

and the toxin is unknown, one option is to use a relatively specific and short-acting β_1 -selective blocker, such as esmolol, because many arrhythmias are a result of excess sympathetic activity. Arrhythmias from stimulant abuse (i.e., cocaine, amphetamines) are predominantly β -adrenergic receptor mediated, and a β -blocking agent is preferred. A nonselective β -blocking drug (i.e., propranolol) could theoretically worsen vasoconstriction, however, by antagonizing β_2 -mediated vasodilation, resulting in unopposed α effects and aggravation of hypertension [68]. Although concerning in theory, studies attempting to identify adverse effects in patients with cocaine-related chest pain treated with nonselective β -blocking drugs have not demonstrated adverse clinical effects [69]. The use of cardioselective (β_1 -receptor-selective) drugs, such as esmolol or metoprolol, avoids this theoretical concern [70].

β -Blocking agents also are preferred for treating tachyarrhythmias from caffeine and theophylline toxicity. Case reports have illustrated that nonselective β -blocking agents can, however, provoke severe bronchospasm in patients with chronic obstructive pulmonary disease (COPD) and asthma [71–74]. Attempts to identify the safety data surrounding β -blockade safety in patients with asthma and COPD are predominantly based on meta-analyses and population-based studies, and their applicability to the treatment of acute poisoning is unclear. Studies of therapeutic administration of β -blocking agents for hypertension have not definitively shown an

adverse effect of β -blocker therapy on FEV1 or respiratory symptoms in patients with COPD [75, 76]. Some evidence exists that the bronchospastic risks associated with COPD may differ from those associated with patients diagnosed with asthma [77]. In the context of β -blocking agent use for control of hypertension in patients with asthma, literature reviews and meta-analyses of the use of these drugs for control of hypertension have demonstrated that although β 1-selective agents may be better tolerated in asthmatics, they are not completely risk-free [78, 79]. Patients with asthma (with or without chronic obstructive pulmonary disease) taking nonselective β -blocking agents may have increased hospitalizations and emergency department utilization [77].

In the absence of data specific to theophylline and caffeine poisonings, esmolol and metoprolol may be considered safer alternatives.

If anticholinergic poisoning is suspected and is associated with hemodynamic instability, β -blockers or physostigmine may be used. Physostigmine, a cholinesterase inhibitor, increases acetylcholine at the neuronal junction, reversing anticholinergic toxicity. Case reports have indicated that physostigmine use in the presence of AV conduction inhibition may worsen AV block, resulting in bradycardia and asystole [80]; however, multiple studies have now demonstrated the safety of physostigmine – in the absence of underlying conduction abnormalities, preceding seizures, or arrhythmias – in reversing delirium and agitation associated with anticholinergic toxicity [81]. Some authors have advocated for dismissal of electrocardiographic criteria entirely in considering the administration of physostigmine for antimuscarinic toxicity [82]; however, the safety of this intervention has not been thoroughly assessed in patients with severe cardiovascular depression from tricyclic antidepressant poisoning. A more extensive discussion of the safety of the use of physostigmine can be found in the chapters on the anticholinergic syndrome and on physostigmine.

Evidence of fast sodium channel blockade on the ECG should be treated with sodium bicarbonate bolus therapy as discussed earlier in the section on WCT and TCA poisoning.

Specific Toxins

Poisonings may result in cardiotoxicity by a variety of mechanisms. To facilitate diagnosis, we categorize the toxins based on manifestations of cardiotoxicity, specifically bradyarrhythmias, tachyarrhythmias, or both. Some poisoned patients also may have abnormalities in conduction without any abnormalities in rate, but the principles of treatment remain the same.

Drugs Causing Bradyarrhythmias

β -Adrenergic Receptor Blockers

β -Adrenergic receptor blockers, with the exception of pindolol, cause cardiac disturbances as a result of β -receptor blockade and typically present with sinus bradycardia and varying degrees of AV block in patients with healthy hearts. Junctional and slow ventricular escape rhythms (heart rate 20–40 beats/min) are seen in patients with underlying conduction disease or with massive overdose. Hypotension, shock, and pulmonary edema resulting from myocardial depression can be seen in any severe β -blocker poisoning but are more likely in patients after massive overdose, or in those with diseased myocardium that depends on sympathetic activity for contractility. Certain β -receptor-blocking drugs have sodium channel blocking effects (acebutolol, pindolol, and propranolol) or sympathomimetic activity (acebutolol and pindolol) that contribute to toxicity [83]. β -Receptor-blocking agents with sodium channel blocking and membrane-depressant effects can cause myocardial depression and conduction system abnormalities, resulting in widening of QRS and hypotension [84]. Sotalol, which has type III antiarrhythmic activity, prolongs the QT interval in a dose-dependent manner and may cause TdP and ventricular fibrillation, even at therapeutic doses [85, 86].

Crystalloid fluids, atropine, and cardiac pacing should be administered initially to patients with bradycardia and hypotension. Glucagon has been the most consistently useful agent in treating severe β -blocker poisonings; however, its efficiency is not based on high-level evidence, and

review articles have questioned its utility [27, 28, 87]. As described above, glucagon activates adenylate cyclase by a non- β -receptor mechanism, enhancing heart rate and myocardial contractility. Epinephrine, dopamine, and isoproterenol also have been used successfully in β -blocker poisoning [26, 88]. Further potential interventions include the administration of high-dose insulin therapy (hyperinsulinemia-euglycemia, HIE), which appears to have positive effects on intracellular glucose transport, vascular dilatation, and increased inotropy based on animal models and multiple clinical cases [89]. In the context of treatment-resistant cardiogenic shock resultant from β -blocker poisoning, animal models and multiple case reports indicate a possible role of intravenous lipid emulsion (ILE) therapy [90]; however, evidence to date is inconclusive to definitively support empiric use of ILE except as possible rescue therapy in severe beta-blocker poisoning refractory to other interventions described above [91, 92]. VA-ECMO has also been used in refractory cases of severe beta-blocker poisoning (see discussion above) [93, 94].

Calcium Channel Blockers

The hallmark of poisoning by verapamil and diltiazem is myocardial depression and hypotension [11]. Sinus bradycardia, varying degrees of AV block, sinus arrest with AV junctional rhythm, and asystole may be seen [95, 96]. Nifedipine, amlodipine, and other dihydropyridines predominantly cause peripheral vasodilation with a reflex tachycardia, but with severe poisoning, they also may reduce myocardial contractility and produce bradycardia [97].

No single treatment consistently reverses calcium channel blocker cardiotoxicity. Atropine, cardiac pacing, and crystalloids can be tried but are often ineffective [98]. Calcium chloride and calcium gluconate reverse the negative inotropic effects of calcium channel blocker toxicity but not AV blockade or peripheral vasodilation (LOE III) [99, 100]. Even high doses of calcium may not be successful in reversing toxicity [17, 101, 102]. Glucagon and epinephrine have produced favorable results in some cases [18, 83]. Based on current evidence from animal studies and case

series, HIE appears to be a superior antidote to calcium, glucagon, and epinephrine and should be considered in recalcitrant or severe cases of calcium channel blocker poisoning (LOE III) [89, 102, 103]. While the precise mechanism of this therapy remains unclear, it appears that the source of energy for the myocardium is altered from free fatty acids to carbohydrates in calcium channel blocker poisoning. High doses of insulin with euglycemia enhance carbohydrate use and the clearance of lactate, improving myocardial contractility in calcium channel blocker poisoning [103]. Calcium channel blockers also inhibit pancreatic insulin release through L-type channel blockade, leading to inadequate carbohydrate use by the myocardium, hyperglycemia, and acidosis. Hyperglycemia in the context of calcium channel blocker overdose – especially with non-dihydropyridines (e.g., diltiazem, verapamil) – is considered to correlate with the severity of intoxication, and has been shown to correlate with in-hospital mortality, the need for temporary pacing, and the need for vasopressor administration [104].

Intravenous lipid emulsion therapy, as discussed above for β -blocker poisonings, has been reported in animal models and case reports to reverse some of the toxicity associated with calcium channel blocker overdose. Although multiple theoretical mechanisms exist, the administration of a large amount of intravenous lipid is thought to form a “lipid sink,” binding, or sequestering lipid-soluble drugs, thereby decreasing their clinical effects. Given the lack of randomized trials and the paucity of specific data, however, this treatment modality should be reserved for cases where the other interventions listed above have been ineffective [90, 105]. A further discussion of this point can be found in the chapter on calcium channel blocking agents.

Studies in animals have found that methylene blue has the potential to increase heart rate, mean arterial pressure, and survival time in an experimental model of amlodipine overdose [106]. This phenomenon has also been illustrated with case reports and is postulated to relate to inhibition of the nitric oxide-cyclic guanosine monophosphate (cGMP) pathway [107, 108]. Recent case studies

Fig. 18 A 73-year-old woman presented with syncope and hypotension after accidentally ingesting three times her normal dose of atenolol. Her initial sinus bradycardia of 36 beats/min did not respond to atropine, and there was no capture with transcutaneous pacing. Glucagon, 3 mg

intravenously followed by a 3 mg/h drip, increased heart rate and blood pressure. Bradycardia and hypotension recurred over the next 8 h with weaning of the glucagon infusion

[109, 110] and some animal data [111–113] have investigated the potential role for the calcium sensitizer levosimendan, currently available in Europe for the treatment of severe decompensated heart failure. VA-ECMO has also been used in the context of calcium channel overdose [54, 114]; please see discussion above. The role of these agents, if any, in the treatment of calcium channel blocker poisoning is discussed further in the chapter on calcium channel blocking agents.

Severe Cocaine and Tricyclic Antidepressant Poisoning

Although cocaine and TCAs primarily cause tachyarrhythmias, severe toxicity may result in ventricular bradycardia with reduced cardiac output and hypotension (Figs. 13 and 18). In addition to sodium bicarbonate, treatment should include cardiac pacing or isoproterenol in conjunction with pressors such as norepinephrine, phenylephrine, or vasopressin. Animal studies have supported the use of lipid emulsion therapy in cocaine toxicity [115]. Although this study involved pretreatment of research animals and is unlikely to translate easily to clinical scenarios

other than massive ingestions, single case reports have shown a potential role for lipid emulsion therapy [116, 117]. Antidotal research for cocaine reversal has been conducted – including cocaine hydrolase, butyrylcholinesterase, and bacterial cocaine esterase – however, novel treatments have yet to be fully studied or marketed [118].

Drugs Causing Tachyarrhythmias

Amphetamines and Cocaine

Amphetamine and many of its analogues release catecholamines from the presynaptic terminals, producing effects through direct stimulation of postsynaptic adrenergic receptors. Cocaine is a potent inhibitor of catecholamine reuptake, which results in increased levels and longer persistence of catecholamines at the adrenergic receptors. Sympathetic overactivity causing sinus or atrial tachycardia and hypertension are common cardiac findings after cocaine or amphetamine use. Compared with amphetamines, cocaine is associated more commonly with cardiovascular complications, such as acute myocardial infarction,

Fig. 19 A 28-year-old man had a seizure in jail 1 h after ingesting crack cocaine. The patient was asystolic when the medic arrived. **(a)** The first electrocardiogram (ECG) was taken on presentation to the emergency department and showed atrioventricular dissociation. **(b)** The second ECG revealed a QRS of 160 ms and a terminal R greater than 3 mm in lead AVR after intravenous fluids and

2 ampules of sodium bicarbonate. **(c)** The third ECG showed sinus tachycardia with resolution of the conduction disturbances. It was recorded after 8 ampules of sodium bicarbonate over 3 h with an improvement of arterial pH from 6.39 to 7.30. The patient recovered fully and was discharged after 5 days of hospitalization

myocardial necrosis, and dissecting aortic aneurysm [119]. Cocaine was implicated in 1.8% of cases from an international aortic dissection registry [120]. Increased myocardial work in the presence of fixed coronary artery disease, cocaine-induced coronary vasospasm, or thrombosis may be responsible for myocardial infarction [121–124], which has been shown to affect up to 6% of cocaine abusers presenting for emergency department care with chest pain [125]. Cocaine use has been associated with premature development of aortic atherosclerosis and hypertension [126]. Cocaine-induced vasoconstriction is augmented by tobacco use [127] and has been experimentally blocked by the α_1 -adrenergic blocking drug phentolamine, suggesting a significant role for α -adrenergic stimulation [128]. Patchy myocardial necrosis and contraction band necrosis as a

result of intense catecholamine stimulation have been described with acute and chronic use of cocaine [122, 123]. The focal areas of necrosis may form a substrate for arrhythmias, which may lead to sudden cardiac death. Myocarditis and cardiomyopathy also have been reported after acute and chronic use of amphetamines and cocaine. Additionally, high doses of cocaine may impede fast sodium channels, resulting in widening QRS, myocardial depression, and hypotension (Fig. 19) [40].

Reported effects of cocaine on cardiac rhythm are listed in Table 5 with a list of proposed underlying mechanisms.

Management of cocaine and amphetamine intoxication should be directed toward specific cardiovascular manifestations [70], including sodium bicarbonate for any ECG manifestations

Table 5 Cardiac dysrhythmias reported with cocaine use, with proposed underlying mechanisms [124]

Dysrhythmias	Mechanisms
Sinus tachycardia	Increased ventricular irritability [129]
Sinus bradycardia	
Supraventricular tachycardia	Sodium channel blockade with inhibition of action potential generation and conduction [130, 131]
Bundle-branch block	
Complete heart block	
Accelerated idioventricular rhythm	
Ventricular tachycardia	Increased intracellular calcium, resulting in afterdepolarizations and triggered ventricular arrhythmias [132]
Ventricular fibrillation	
Asystole	
Torsade de pointes	
Brugada pattern (right bundle-branch block with ST-segment elevations in leads V ₁ , V ₂ , V ₃)	Reduced vagal activity, thus decreasing parasympathetic control of tachycardia [133]

of sodium channel blockade (LOE III). Animal studies have shown benzodiazepines to reduce mortality from psychomotor agitation as a result of cocaine toxicity [134]. Benzodiazepines should be first-line therapy for treatment of agitation, tachycardia, and hypertension in these patients (LOE III) and should be accompanied by intravenous fluids, oxygenation, and cooling, as clinically indicated [135]. Persistent severe hypertension or hypertension with end-organ damage can be treated with vasodilators, such as sodium nitroprusside or α - and β -blocking drugs. Treatment for arrhythmias has been discussed in a prior section.

Anticholinergics

Anticholinergic drugs competitively inhibit acetylcholine at its muscarinic receptor sites and produce the well-described anticholinergic syndrome. By blocking the cholinergic effects on the heart, these drugs cause sinus tachycardia with mild hypertension. Serious arrhythmias from anticholinergic agents are rare, unless patients have underlying cardiac disease (i.e., severe coronary artery disease with tachycardia-induced ischemia), or the ingested compound has other

cardiotoxic properties in addition to muscarinic blockade. Common medications with anticholinergic effects that also cause conduction abnormalities in overdose include TCAs, phenothiazines, and antihistamines, all of which are discussed individually elsewhere in this book. Management of tachyarrhythmias from anticholinergic toxicity has been discussed previously.

Antihistamines

Most antihistamines have some degree of anticholinergic activity and produce varying degrees of the anticholinergic syndrome after overdose. Additionally, other properties of these agents can cause primary cardiac disturbances. Fast sodium channel blockade may result in slowing of conduction and wide QRS, which should be treated similar to TCA poisoning. This condition has been reported most commonly with diphenhydramine. Two antihistaminic agents, terfenadine and astemizole, inhibit outward potassium currents, causing QT interval prolongation and occasionally TdP. This condition can occur if the parent compound builds up as a result of impaired metabolism secondary to hepatic dysfunction or drug interaction or in overdose. For example, terfenadine produces dose-related QT prolongation. Terfenadine concentrations are normally below the arrhythmia-inducing threshold due to rapid metabolism via cytochrome P450 CYP3A4. Coadministration of CYP3A4 inhibitors (e.g., ketoconazole) increases concentrations of terfenadine, which may result in significant QT prolongation and torsade de pointes. Although terfenadine and astemizole have been withdrawn from US markets, they serve as an example of adverse cardiovascular effects that can be precipitated by drug-drug interactions. Management of prolonged QT interval and TdP is described elsewhere in this chapter.

Tricyclic Antidepressants

Hypotension, tachyarrhythmias, and seizures are the most frequently encountered signs of toxicity from TCA poisoning [136]. Manifestations of toxicity are a result of various mechanisms, including anticholinergic properties, catecholamine reuptake

inhibition, fast sodium channel blockade, and peripheral α_1 -blockade [137, 138]. Early in overdose, patients usually manifest sinus tachycardia as a result of anticholinergic effects and increased circulating catecholamines. With more severe poisoning, patients manifest signs of fast sodium channel blockade with impairment of conduction and myocardial depression. Peripheral α_1 -blockade, depressed inotropy, and catecholamine depletion all may contribute to hypotension.

ECG changes often precede cardiovascular deterioration, and the ECG is used widely as a bedside tool in assessment and risk stratification of patients with possible TCA poisoning [35]. Aside from anticholinergic effects causing sinus tachycardia, most other ECG findings in TCA poisoning (e.g., wide QRS, prominent R wave in AVR) result from fast sodium channel blockade and have been discussed in a prior section. Bundle-branch block-like pattern, AV block, ventricular bradycardia, and asystole also may be seen with severe toxicity [33]. The absence of conduction inhibition does not rule out TCA poisoning because hypotension can occur with or without conduction inhibition [139].

WCTs and intractable hypotension are the two most common reasons for death after TCA poisoning [138]. As described previously, manifestations of membrane depression that benefit from sodium bicarbonate include QRS widening greater than 100–120 ms, hypotension, and ventricular arrhythmias. Hyperventilation may be beneficial, but only transiently and only in cases in which sodium bicarbonate is not readily available or contraindicated (i.e., pulmonary edema).

Hypotension without evidence of conduction inhibition often can be treated with isotonic crystalloids [138]. If pressors are required, norepinephrine, phenylephrine, and/or vasopressin is the recommended vasoconstrictor agent. Profound cardiogenic shock with intractable hypotension is encountered occasionally in TCA poisoning and is associated with a high mortality. Intra-aortic balloon pump or arteriovenous extracorporeal membrane oxygenation/cardiopulmonary bypass may be the only means to stabilize these patients until their bodies can metabolize the TCA [140].

In addition to TCAs, several other drugs possess “quinidine-like,” membrane-depressant properties (see Table 1). Many of these other agents do not possess anticholinergic or sympathomimetic properties and do not manifest sinus tachycardia as with TCAs, cocaine, or antihistamines.

Caffeine and Theophylline

Caffeine and theophylline poisoning cause nonselective β -adrenergic stimulation through systemic and local catecholamine release. Additionally, at high concentrations, they inhibit phosphodiesterase, an enzyme that degrades cAMP, synergistically enhancing β -adrenergic stimulation. Cardiovascular manifestations of caffeine or theophylline intoxication commonly include SVTs and VTs in addition to hypotension. Early in the course of poisoning, hypotension may be due to direct vasodilation, but prolonged catecholamine stimulation resulting in myocarditis and impaired contractility can occur later. Additionally, older patients with ischemic heart disease can have myocardial depression as a result of ischemia aggravated by tachycardia and hypotension. Convulsions and metabolic abnormalities (hypokalemia, acidosis) also contribute to arrhythmias and hypotension.

Management is often difficult because patients on theophylline are generally older and have chronic lung disease. Management of tachyarrhythmias has been discussed. Hypotension may resolve with judicious use of fluids, treatment of arrhythmias, and correction of metabolic abnormalities. Pressors may be required for recalcitrant hypotension. Nonselective β -blockers, such as propranolol, can reverse hypotension by blocking β_2 -mediated vasodilation. β_1 -Selective blockers, such as esmolol and metoprolol, are preferred in the presence of bronchospastic lung disease; in addition, infusions of esmolol are easily titrated and are thus preferred in the context of acute severe caffeine ingestion.

Drugs Causing Either Tachyarrhythmias Or Bradyarrhythmias

Cardiac Glycosides

Digitalis has a variety of pharmacologic properties that result in protean manifestations of

toxicity. In overdose, morbidity and mortality may result from arrhythmias, heart block, and hyperkalemia. Disruption of sodium and potassium transport, with the associated hyperkalemia, depresses conduction velocity [14]. Increased rate of diastolic depolarization and delayed ADs may cause ventricular ectopy or tachyarrhythmias. Additionally, digitalis may enhance sympathetic activity, causing increased automaticity while decreasing parasympathetic activity and consequently accelerating conduction velocity. Resultant arrhythmias in overdose often are characterized by increased automaticity and depressed intracardiac conduction. The development of an atrial tachycardia with 2:1 or higher-degree AV conduction block suggests digitalis toxicity. AV junctional tachycardia and ventricular ectopy, tachycardia, or fibrillation may be more common in patients with diseased hearts [15]. Bradyarrhythmias, including sinus bradycardia, second-degree and complete AV block, atrial fibrillation with slow ventricular response, idioventricular rhythm, and asystole, also can occur with digitalis poisoning. Hyperkalemia, resulting from inhibition of sodium-potassium exchange, can contribute to AV block and depressed excitability and is an indicator of poor prognosis.

First-line treatment for arrhythmias or hyperkalemia in digitalis poisoning is administration of digoxin-specific antibodies (LOE I) [141]. If the antibodies are not immediately available, temporizing measures should be directed at the specific arrhythmia and normalization of serum potassium levels. Insulin, glucose, and bicarbonate are preferred treatment for digitalis-induced hyperkalemia. Lidocaine and phenytoin may ameliorate tachyarrhythmias by increasing AV conduction and depressing automaticity (LOE III) [15]. Cardiac pacing should be reserved for high-grade AV blocks and bradyarrhythmias with hemodynamic compromise because some evidence suggests that pacing may enhance triggered rhythms due to delayed ADs [8, 9]. Although esmolol can be used for tachyarrhythmias, other β -blockers, calcium channel blockers, and type Ia antiarrhythmics should be avoided because they can worsen conduction

disturbances [15]. These poisonings are discussed in greater detail in the chapter on digitalis glycoside poisoning.

Type I Antiarrhythmics

In overdose, type Ia antiarrhythmic drugs block fast sodium channels, impede slow inward calcium and outward potassium channels, and reduce the rate of spontaneous depolarization [142]. ECG findings may include QRS widening, bundle-branch block, SA or AV block, and marked QT prolongation. Patients may present with bradycardia resulting from conduction delay and block [36]. Monomorphic VT from reentry as a result of membrane depression and PVT as a result of prolonged repolarization can occur with type IA (quinidine) poisoning (overdose and sometimes with therapeutic doses). Hypotension also is a common manifestation secondary to depressant actions on the heart. Similarly, type IC antiarrhythmics (flecainide, propafenone) cause bradyarrhythmias with conduction delays, depressed inotropy, and shock and monomorphic VT in overdose. The effects of these agents on cardiac conduction are rate dependent, so the extent of QRS widening is greater at faster heart rates. Recognition and management of conduction inhibition and hypotension are similar to that discussed in the previous section on TCAs. Treatment of PVT also is described elsewhere in this chapter. Poisoning by these agents is discussed in greater detail in ► [Chap. 39, “Sodium Channel-Blocking Antidysrhythmics”](#).

Antipsychotic Drugs

Cardiovascular manifestations of antipsychotic agents in overdose result from a combination of α -adrenergic blockade, anticholinergic activity, and “quinidine-like,” membrane-depressant effects. Although these properties appear to be similar to TCAs, individual antipsychotic agents have varying potencies and different degrees of concentration in the myocardium. Most predominantly possess α -adrenergic and anticholinergic properties, the cardiovascular toxicity of which generally is not difficult to treat. Thioridazine and mesoridazine are the most cardiotoxic neuroleptics and have been responsible for most

deaths from this group [143]. Their membrane-depressant effects and ECG manifestations are similar to those described for type IA antiarrhythmics. Bradycardia with SA or AV block, prolonged QT interval, QRS widening, and bundle-branch blocks may occur in overdose [144]. Sinus tachycardia due to anticholinergic properties also may be seen with thioridazine and mesoridazine but not as predictably as with TCAs or with some of the other neuroleptics. Monomorphic VT and PVT have been reported with these neuroleptics [145]. TdP is reported more commonly with neuroleptics than with TCA overdose [143]. A likely explanation is that TCA-poisoned patients are frequently tachycardic because of the anticholinergic effects, which may be less prominent in thioridazine or mesoridazine overdose and are absent in quinidine poisoning. Because TdP is “pause dependent,” and repolarization time is inversely proportional to heart rate, patients with bradyarrhythmias in the presence of these neuroleptics may be more likely to develop PVT (see Fig. 13). Treatment for PVT is described elsewhere. Conduction abnormalities and hypotension should be treated as with type Ia antiarrhythmics and TCA poisoning. Second-generation or atypical antipsychotics – including aripiprazole, risperidone, ziprasidone, quetiapine – have a broad range of pathophysiologic effects but have much fewer adverse cardiovascular effects in overdose when compared to earlier antipsychotics. A systematic review of the toxicity associated with aripiprazole, olanzapine, quetiapine, risperidone, and ziprasidone found some cases associated with QTc prolongation and dysrhythmias but concluded that the cardiotoxicity of these compounds is overall quite low [146]. Quetiapine in particular has been associated with QTc prolongation and torsade de pointes [147] and has been associated with sometimes profound, transient hypotension and tachycardia in multiple cases [148, 149], presumably due to this compound’s alpha-adrenergic and histamine blockade.

Poisoning with antipsychotic drugs is discussed in greater detail in the chapter on antipsychotic agents.

Summary

Central to the treatment of critically poisoned patients is initial stabilization using the clinical approach outlined in this chapter followed by a thorough history, physical examination, and evaluation of the ECG. Autonomic disturbances, membrane-depressant effects, triggered rhythms, and systemic metabolic influences may contribute to cardiac conduction and rate disturbances in poisoned patients. Recognition of these disturbances facilitates further management of patients manifesting signs and symptoms of cardiotoxicity from an unknown drug or a poison.

Torsade de pointes (TdP) is a rare but potentially life-threatening event in poisoned patients. The medical toxicologist must identify high risk patients and recognize preattack electrocardiographic (ECG) signs and be able to rapidly distinguish this arrhythmia from other ventricular arrhythmias as the treatment of TdP is unique. This chapter emphasizes the pathophysiology, risk factors, ECG signs, and clinical management of TdP in the poisoned patient as well as the clinical approach to QT-prolongation in poisoned patients.

Background

Dessertenne introduced the term “torsade de pointes” in 1966 when he described the strange appearances of an intermittent rapid arrhythmia in a woman with bradycardia [1]. TdP implies a continual change in the amplitude of the QRS complexes, which appear to twist around an isoelectric line (Fig. 1). He also described T wave abnormalities in the ECG before and in between the bouts of TdP. The striking ECG features of this arrhythmia had been previously reported in the 1920s [2]. TdP is a pulseless polymorphic ventricular arrhythmia that occurs in patients with a significantly prolonged repolarization phase reflected electrocardiographically as a prolonged QT interval. Prolonged QT intervals (reflecting prolonged repolarization) may be due to drugs,

Fig. 1 An arrhythmia recording of a woman 5 h after an acute overdose of citalopram showing sinus rhythm with a prolonged QTc-time and frequent extrasystoles followed

by a typical TdP. The patient was later diagnosed with a congenital LQTS

congenital, electrolyte abnormalities, cardiac disease, or often a combination of these etiologies [3]. There is a growing list of drugs that have been associated with QT prolongation. Some of these drugs have also been associated with TdP, and recent drug withdrawals in several countries because of this severe side effect (quinidine, thioridazine, cisapride, and terfenadine) have underscored the importance of recognizing the potential of some QT prolonging drugs to cause TdP.

Pathophysiology

Action potentials reflect the diffusion of ions across the cardiac cell membrane from areas of high concentration to areas of low concentration. The movement of ions creates a current which determines the morphology and duration of the cardiac action potential. An action potential is initiated when a resting myocyte is depolarized causing the sodium channels to open and sodium ions to move into the cell. The resulting change in transmembrane potential generates a series of subsequent openings and closings of other ion channels. Action potential duration (APD) is heterogeneous throughout the anatomic regions of

the heart due to variability of genetic expression of both ion channels and transport pumps. The ECG intervals are a surface reflection of cardiac ionic movements. The duration of the QT interval on the ECG is representative of the time required by the ventricular myocytes to repolarize. A prolonged QT interval is seen when the repolarization time is increased in a significant number of myocytes (Fig. 2).

Implications of drugs: Some drugs may increase repolarization time (and therefore APD) by blocking the outward potassium rectifier current (IKr) leading to a decreased outward potassium flow during phase 2 or phase 3 of the action potential (Fig. 3). The net outward current is decreased, yet the inward cationic current continues to increase (as voltage decreases at the end of phase 2 and during phase 3) causing an early after depolarization (EAD) to be propagated [4]. The prolonged refractory period resulting from delayed repolarization renders the myocardium vulnerable to reentrant tachyarrhythmias. If an EAD reaches threshold value, premature ventricular contractions (PVC) occur. The PVC propagates slowly through incompletely recovered myocardium potentially forming a functional reentrant circuit and triggered automaticity. If a drug causes EADs and dispersion of cardiac repolarization (so-called heterogeneity

Fig. 2 Ionic movement across cardiac membranes associated with prolonged QT interval

Fig. 3 Time course of currents during the action potential. Note drugs block delayed K rectifier current

Fig. 4 Pathogenesis of early after depolarizations (EADs)

EAD's - Mechanism

of intracardiac repolarization), TdP may occur [5] (Fig. 4).

The three cell types in the ventricular myocardium normally have different repolarization characteristics and therefore differing APDs. This intrinsic difference is termed intrinsic transmural heterogeneity of cellular repolarization. Drugs that block I_{Kr} do so to varying degrees in each cell type. The resulting increased differences in repolarization rate and APD among the cell types may cause unidirectional conduction block and intramural reentry, so-called torsade de pointes.

Risk Drugs for Torsade de Pointes

An immense number of drugs prolong repolarization and increase the QT interval [6], but few actually cause TdP. Risk drugs are listed on the credible Meds website, which has become the standard reference (<https://www.crediblemeds.org>) [7]. Several drugs that cause TdP have been removed from the market. In Sweden, for instance, only a handful drugs that have the potential to cause TdP are still available for oral use, namely, sotalol, disopyramide, chloroquine, quinine, methadone, and citalopram. Drugs such as amiodarone, erythromycin and haloperidol have a strong ability to prolong the QT interval, but do not induce TdP after an oral overdose in the

absence of other major risk factors. It should be noted, however, that a few other true risk drugs, as for example amisulpride, may be available in other parts of the world. Most of the drugs that have been associated with QT prolongation in therapeutic dosage or overdose, e.g., quetiapine, olanzapine, risperidone and lithium, do not induce TdP even in overdose [8, 9].

Risk Factors for Torsade de Pointes in Poisoned Patients

Major risk factors: Clinically, the most important risk factors for TdP are as follows:

- A prolonged QT interval is a prerequisite of development of TdP, and at least for some drugs (e.g., amisulpride), it has been shown that also the extent of the QT prolongation is a risk factor [10].
- Bradycardia [11]. The majority of published cases of drug-induced TdP had a heart rate below 80 beats per minute (bpm) when the torsade occurred [12].
- Hypokalemia [12, 13].
- Multiple major risk factors in a single patient [14].

An important risk factor in the setting of poisoning is the specific drug and the dose that has

Table 1 Major risk factors for torsade de pointes in poisoned patients

Ingestion of a toxic dose of a high risk drug
QTc >500 ms or a QT–HR pair above the QT nomogram “risk line”
Bradycardia
Hypokalemia
Multiple major risk factors

been ingested. This implies that at a certain degree of QTc prolongation, the risk for TdP is much greater if a patient has overdosed on a high risk drug such as sotalol or amisulpride compared to a drug with a lesser risk of causing TdP such as haloperidol (Table 1).

Other risk factors: Examples of other risk factors for TdP are as follows:

- Female gender. Many studies have shown an approximately twofold higher risk for drug-induced TdP among women [14, 15].
- Hypomagnesemia and hypocalcemia [14, 16]. A low serum calcium will prolong the QT interval, but the evidence for hypocalcemia being a significant risk factor for TdP is weak [14].
- Structural heart disease such as congestive heart failure or cardiomyopathy increases risk [11, 14].
- Congenital long QT syndrome and other genetic susceptibilities. Approximately 10–15% of patients with drug-induced TdP have been shown to have some genetic marker [14, 17]. Thus, genetic susceptibilities for TdP may be an important risk factor among poisoned patients even though the genetic disturbance is often unknown at presentation.
- Finally, advanced age and ingestion of more than one QT prolonging drug increases the risk for TdP [15, 18] (Table 2).

Methods for Measurement of the QT Interval

Manual or automatic: There are several manual and automatic methods described for accurate measurement of the repolarization duration on

Table 2 Other risk factors for torsade de pointes

Female gender
Advanced age
Hypomagnesemia
Structural heart disease
Congenital LQTS
Ingestion of several QT prolonging drugs

the ECG. A major problem for all methods is defining the end of the T wave, especially in tachycardia. Other controversial issues for all approaches are: should measurement be performed in one or multiple ECG leads and in one or multiple beats in each lead, and if multiple leads and beats should be measured, which value should be used, the highest, the mean or the median? The manual approach has the advantage of more accurately determining the end of the QT interval, but is considerably more time-consuming as measurements in up to 6 different ECG leads and 3–5 beats in each lead are often recommended. Contemporary automatic QT-monitoring systems allow the rapid measurement of large numbers of QT intervals but may be inaccurate in determining the end of the T wave, and some serious miscalculations by different ECG monitors have been published [19, 20].

Heart rate correction: The strong effect of the heart rate on the QT interval makes heart rate correction necessary. The by far most commonly used correction method worldwide is “Bazett’s QTc” ($QTc = QT \text{ interval (ms)} / RR \text{ interval (s)}^{0.5}$) [21, 22]. Other less common methods are Friderica’s, Hoge’s and Framingham’s formulas. Most experts consider a QTc value above 500 ms as a significant risk of TdP [11, 14, 19]. The weakness of Bazett’s method in particular is that the QTc value is overestimated in tachycardia and underestimated in bradycardia [19].

The QT interval nomogram: To overcome the weaknesses of the different correction formulas, Chan and colleagues developed a QT interval nomogram [12] (Fig. 5). The nomogram is based on a cloud diagram produced by Fossa and colleagues [23]. Chan and coworkers evaluated the performance of this QT nomogram by comparing

Fig. 5 The QT interval nomogram. The “risk-line” separates QT-HR pairs below the line from those above which are associated with an increased risk of TdP (Reproduced from Ref. [12], with permission)

QT-HR combinations from 129 published cases with drug-induced TdP and 318 control cases poisoned by noncardiotoxic drugs [12]. This study reveals that the QT nomogram has a high sensitivity and specificity, somewhat better than Bazett's QTc equal to 500 ms, but it also shows that Bazett's correction formula with a risk cutoff at 500 ms also do quite well and, in fact, is similar to the QT nomogram for heart rates between 70 and 100 bpm. Moreover, the study reveals that a vast majority of all cases of drug-induced TdP occur in patients with a heart rate below 80 and that extremely few occur in tachycardic patients.

How to Best Measure the QT Interval

Isbister concluded in a recent review [19] that the most accurate method is to perform manual measurements of QT intervals. He recommends measurements in six different ECG leads and then using the median value for insertion into the QT nomogram. While this method may be used in clinical studies, and by consulting medical toxicologists and cardiologists, this rather time-consuming approach is not practical in the acute clinical setting of the poisoned patient. It is reasonable that the routinely performed supervision and monitoring of poisoned patients include automatic measurements of QTc values. However, for patients with a suspected overdose of a high risk

drug or with a QTc value above 500 ms at a heart rate below 100 bpm, Isbister's method may be preferred. Irrespective of the chosen method for measurement of the QT interval, one must realize the fact that the QRS complex is included in the calculation. This “weakness” of the QT interval per se becomes obvious in patients with bundle branch block or poisoning with drugs that also have membrane stabilizing properties.

Management of QTc Prolongation in Poisoned Patients

If a poisoned patient has overdosed on a drug known to carry a risk of TdP or display a QTc prolongation on the 12-lead ECG, continuous ECG monitoring and repeated measurements of the QT interval are imperative. Serum levels of potassium and calcium should be checked and corrected to the mid-reference range. Other possible risk factors should be considered. Drug-drug interactions and heart rate must be considered. An external defibrillator should be readily available. The patient should not be transported from the unit for diagnostic or therapeutic procedures unless monitored and accompanied by personnel able to respond to the development of TdP.

Prophylactic treatment: Recommendations regarding prophylactic pharmaceutical treatment of poisoned patients with a presumed high risk of developing TdP are controversial and almost

lacking [24, 25]. However, several clinicians and clinical toxicologists agree that magnesium administration may be indicated in certain high risk cases [22, 24]. If, for example, a patient has ingested a toxic dose of a high risk drug such as methadone or sotalol and displays a QTc-time above 500 ms at a heart rate below 80 bpm, it seems reasonable to administer 2 g magnesium (8 mmol) as an intravenous bolus injection over 5 min followed by an infusion of 1 g magnesium/h for 4–6 h. Arguments for this approach are that magnesium therapy is an effective treatment of TdP, suppresses EADs, and is well tolerated in the recommended dose range. In these relatively few high risk cases, there may also be a role for the administration of atropine and isoproterenol if significant bradycardia is present (see “Guidelines” section below). However, the routine use of magnesium in every patient with a QTc interval over 500 ms or with a QT–HR pair above the “risk line” is definitely not justified. For example, magnesium supplementation would not be indicated if the patient is tachycardic or if a nonrisk drug such as quetiapine, olanzapine, or risperidone has been overdosed.

Management of Toxicant-Induced Torsade de Pointes

The attack: The characteristic pattern of an attack of TdP is a pulseless polymorphic ventricular tachycardia, typically with short-lived intermittent runs interspersed with pulse-yielding beats (Fig. 6a and b). This means that the patients are most often asymptomatic during the arrhythmia, although they may experience palpitations, dizziness, or short-lived syncope [3, 14, 15, 26]. Cardioversion is seldom needed, indicated, or successful as long as the TdP-runs may not become persistent or degenerate to ventricular fibrillation.

Management of torsade de pointes: Because of the rarity of TdP, there is no evidence regarding its treatment derived from controlled trials. Magnesium (Mg) suppresses TdP although its mechanism of action is not fully understood. Magnesium

is a potassium channel blocker. As the electrochemical gradient of the cardiac cell promotes outward movement of potassium via IKr, Mg blocks the outward flow of potassium maintaining the action potential plateau. Nevertheless, magnesium is also a natural calcium channel blocker. Decreasing the inward calcium current suppresses EADs without affecting the QT interval. Magnesium also homogenizes transmural ventricular dispersion which causes repolarization to approach the normal intrinsic variability [27].

Guidelines: Published recommendations and guidelines for the management TdP recommend slight variations of the following protocol which is supported by numerous clinical observations and case series [3, 5, 14, 15, 28, 29].

- The first appropriate action, after basic life support procedures have been initiated, is to administer an intravenous bolus of 2 g (8 mmol) magnesium over 2 min, irrespective of the serum Mg concentration (Level of Evidence [LoE]: II-3).
- Secondly, correct hypokalemia (LoE: II-3), with the aim of achieving a serum potassium concentration of 4.5–5.2 mmol/L (LoE: III) [3, 29].
- If the TdP-runs do not resolve after these measures, we recommend an additional 2 g of Mg to be administered over 5 min (LoE: II-3).
- In cases where the preattack heart rate was slow, for example, below approximately 70 bpm, a dose of atropine can be administered and an isoproterenol infusion should be initiated (dose range: 0.03–0.3 µg/kg/min) (LoE: II-3). Overdrive pacing is indicated if the TdP continues or isoproterenol is contraindicated or not tolerated (LoE: II-3).
- It is often appropriate to start an intravenous infusion of 1 g (4 mmol) magnesium/h as the half-life of magnesium is only approximately 4 h.
- If pulseless unconsciousness occur, immediate cardioversion is indicated (Table 3). Transcutaneous pacing pads, placed after the first sign of TdP, are useful to have in place in case they are needed for the management of a sustained event.

Fig. 6 (a and b). Two arrhythmia recordings showing the characteristic pattern of torsade de pointes with short-lived runs interspersed with pulse-yielding beats

Table 3 Treatment of toxicant-induced torsade de pointes

Slow iv. injection of 2 g magnesium (8 mmol)
Correct hypokalemia to the upper reference limit
If TdP-runs proceed, give another 2 g magnesium iv.
If preattack HR is slow, start isoproterenol and consider overdrive PM
Consider an infusion of 1 g magnesium per hour for 6 h
If prolonged pulseless unconsciousness occur, defibrillate

The anticholinergic syndrome is common and may result from exposures to many drugs or natural substances (Table 1). Anticholinergic effects are desired or intended effects for certain drugs (i.e., antispasmodics, mydriatics, and belladonna alkaloids) and are undesired or side-effects for other drugs (i.e., antihistamines, antidepressants, antipsychotics, and antiparkinsonians). Both prescription and over-the-counter drugs may have anticholinergic effects. Combined use of more than one drug with anticholinergic effects increases the risk of anticholinergic toxicity. The anticholinergic syndrome, also called the *anticholinergic toxidrome*, has peripheral and central manifestations. The more serious adverse effects associated with large exposures to these agents are often a result of other physiologic properties of these agents rather than the anticholinergic effects.

Granacher and Baldessarini [3] and Hall and colleagues [4] were among the first to describe the central anticholinergic syndrome (CAS), a sometimes dramatic form of anticholinergic toxicity in which central nervous system (CNS) effects occur in the absence of peripheral anticholinergic manifestations. As with all anticholinergic syndromes, CAS may result from abuse, intentional or unintentional overdoses, or adverse drug reactions. A moderate stage of anticholinergism with euphoria and hallucinations is the desired end point of certain forms of substance abuse, but achieving the desired stage of intoxication and avoiding toxicity is difficult.

Overview and Incidence

Data from the American Association of Poison Control Centers National Poison Data System indicate that anticholinergic exposures are common but usually not severe or fatal (Table 2) [5]. Of the more than 97,000 exposures reported in the United States in 2013, only one third of cases were treated in a healthcare facility (Table 3). These data, compared to AAPCC data from 2002,

demonstrate a marked decrease in reported exposures and deaths from anticholinergic exposure in 2014 [5, 6]. Use of drugs with anticholinergic activity is the most common cause of pharmaceutical-induced delirium [7]. Differences in clinical effects result from not only the dose but also variability in the degree of muscarinic receptor blocking among agents [1, 2]. Large intentional ingestions of sleeping pills, antihistamine-type sleeping pills, and tricyclic antidepressants (TCAs) are common causes of serious toxicity within these groups. Antihistamine exposure is the most common cause of unintentional anticholinergic toxicity, whereas cyclic antidepressants and atypical antipsychotics are proportionally larger origins of intentional exposures and toxicity [6]. Many anticholinergic-type adverse drug reactions and abuse are not reported to poison centers or adverse drug reaction programs, and their true incidence is unknown. In one study, 60% of elderly nursing home patients were taking at least one anticholinergic agent, and 13% of patients on anticholinergic drugs in one geriatric unit had significant adverse effects [7]. Data from the American College of Medical Toxicology's Toxicology Investigators Consortium (ToxIC) Case Registry reveal that of patients requiring medical toxicologist-directed treatment, 6% of patients age 19–65 years and 4% of patients age greater than 66 years had anticholinergic toxicity [8].

History

Natural substances with anticholinergic properties, such as nightshade plants, have long been used for their mind-altering properties by different cultures [9]. The Solanaceae alkaloids, primarily atropine and scopolamine, have been the active ingredients of ancient witches' brews and ointments (Pharmaka diabolica), love potions, intoxicants, hallucinogens, knockout agents, and poisons. British soldiers were described as "natural fools" for 11 days after consuming a salad containing leaves of *Datura stramonium* (Jimson weed) (see ► Chap. 111, "Anticholinergic Plants") [10].

Pathophysiology

Acetylcholine (ACh) is a key neurotransmitter in both the central and peripheral nervous system. When released, ACh may activate either nicotinic or muscarinic receptors (Fig. 1). Nicotinic receptors (12 types: α_2 – α_9 and β_2 – β_5) are located in the CNS (mainly spinal cord), on postganglionic autonomic neurons (sympathetic and parasympathetic), and neuromuscular junctions. These receptors are ligand-gated ion channels for sodium (Na⁺) and calcium (Ca²⁺), activation of

which leads to rapid cell membrane depolarization and cellular excitation.

Muscarinic receptors, however, are located in the CNS (mainly brain (Fig. 2)), end-organ parasympathetic nerve endings, sympathetically innervated sweat glands and, to a lesser extent, autonomic ganglions and the adrenal medulla [11, 12]. There are five types of cloned muscarinic receptors (M₁ through M₅), whose effects are mediated more slowly than nicotinic receptors through guanosine triphosphate-binding proteins (G proteins). The primary intracellular messengers

Fig. 1 Cholinergic signaling in neurons and bronchial epithelial cells. **(a)** In neurons, choline for ACh synthesis is transported by the choline high-affinity transporter (CHT1). ACh is then synthesized by the action of choline acetyltransferase (ChAT) and packaged into synaptic vesicles by the action of the vesicular acetylcholine transporter (VACHT) and CHT1. ACh is then secreted by the complex processes that control synaptic release. Released ACh then interacts with postsynaptic nAChR and mAChR as well as presynaptic receptors. Signaling is terminated by acetylcholinesterase (AChE) and butyrylcholinesterase (BChE). Key signal transduction events lead to the generation of action potentials, opening of membrane and internal ion channels, muscle contraction and kinase activation. **(b)** In bronchial epithelial cells (BEC), though CHT1 is present,

CHT1 does not appear necessary for choline transport for ACh synthesis. In BEC, as for neurons, ChAT is utilized for ACh synthesis; though there are multiple isoforms of ChAT, different splicing products may be utilized in different cell types. Since CHT1 is not required and BEC do not have synaptic vesicles, the role of VACHT and CHT1 in ACh secretion is unknown, though both are expressed in BEC. ACh released by BEC is inactivated by the same cholinesterases as expressed in neurons. A key difference is that released ACh is not limited just to synaptic communication but can also signal multiple neighboring cells as a paracrine factor or more distal cells as a hormone (From Handbook of Experimental Pharmacology Vol 208. Fryer AD et al. eds, 2012, Springer, Munich, with permission)

affected by muscarinic stimulation are Ca^{2+} and cyclic adenosine monophosphate (cAMP). Odd-numbered receptors (M_1 , M_3 , M_5) activate a G protein that leads to the release of intracellular calcium, resulting in smooth muscle contraction and gland secretion. Even-numbered receptors (M_2 , M_4) activate a G protein that inhibits adenylyl cyclase, leading to reduced levels of cAMP. Thus, the intracellular effects of muscarinic stimulation may lead to either stimulatory (depolarizing) or inhibitory (hyperpolarizing) effects on membrane potentials depending on the receptor types present on any particular structure [13]. After release, ACh undergoes synaptic degradation via acetylcholinesterase (AChE) into the inactive products choline and acetate.

Toxic Mechanism

Anticholinergic agents antagonize the effect of ACh by competitively blocking its binding to either nicotinic or muscarinic ACh receptor sites. Clinically significant nicotinic ACh receptor blockade results in neuromuscular paralysis and is most commonly encountered with the usage of paralytic agents including depolarizing agents (e.g., succinylcholine) and nondepolarizing curare-mimetic agents (e.g., pancuronium). Symptoms of nicotinic ACh antagonism may also arise from elapid envenomation due to the effect of α -neurotoxins [14].

Until recently, significant nicotinic ACh antagonism from nicotine ingestion was uncommon.

Fryer AD et al. eds, 2012, Springer, Munich, with permission)

However, between 2010 and 2016, there has been rapid development and expanded use of electronic nicotine delivery systems (e.g., electronic cigarettes). These systems vaporize liquid nicotine preparations from chambers that are often filled by hand from a commercially available bottle of concentrated nicotine fluid. Appealing flavorings and colorful labeling conflict with poor regulation of packaging, likely contributing to a staggering rise in liquid nicotine exposure reporting to the AAPCC, with more than half of the 3,073 exposures in 2015 occurring in children under 6 years of age. These figures are compared to 2011 in which there were only 271 total reported exposures [15]. Unfortunately, there has been similar rise in published case reports of pediatric ingestions resulting in significant toxicity and death [15, 16].

Muscarinic ACh receptor blockade is commonly encountered and makes up the bulk of clinically significant exposures, so much so that

the so-called anticholinergic toxidrome may be more appropriately characterized as an *antimuscarinic toxidrome*. Effects of muscarinic ACh blockade may be divided into central and peripheral effects (Table 4). Generally, central antimuscarinic activity results in changes in mentation including agitation, picking movements, and hallucinations and peripheral antimuscarinic activity results in anhidrosis, mydriasis, tachycardia, and urinary retention. These effects are often dose-dependent, with low level antagonism resulting in decreases in sweating as well as bronchial and salivary secretion production. Moderate antagonism may result in tachycardia and mydriasis with resultant loss in visual accommodation [17]. Urinary retention and intestinal/gastric atony result from high degree peripheral muscarinic ACh antagonism [12]. Muscarinic receptor antagonists (e.g., atropine) are generally ineffective at blocking nicotinic sites. Tertiary agents more readily cross the blood–brain barrier and are

more likely to result in central anticholinergic toxicity, whereas the converse is true of quaternary agents (Table 5). Atropine typically causes predominantly peripheral anticholinergic effects at low doses and additional central anticholinergic effects at higher doses [17]. Still higher doses of atropine may result in shock, coma, and respiratory failure [18]. Quaternary antimuscarinic compounds do not readily cross the blood–brain barrier and are unlikely to result in central ACh nicotinic blockade.

Pirenzepine	Ipratropium
Tolterodine	Mepenzolate
	Propantheline

Clinical Presentations and Life-Threatening Complications

The anticholinergic toxidrome is a constellation of signs and symptoms potentially involving many different organ systems (see Table 4). Signs of peripheral anticholinergic toxicity characteristically, but not always, accompany central anticholinergic toxicity. The authors of a carefully controlled clinical study meticulously described the onset and course of iatrogenic central anticholinergic toxicity and its reversal by the cholinergic agent physostigmine [19]. They described three phases: induction, stupor, and delirium. In the induction phase, peripheral anticholinergic effects predominated. The stupor phase was characterized by somnolence, restlessness, ataxia, hyperthermia, and hypertension. The third phase, delirium, was characterized by amnesia, confusion, incoherent speech, and hallucinations. These phases represent an overlapping continuum of toxicity rather than distinct transition points. Importantly, the delirium phase often outlasted the first two phases. These phases were described in the setting of central anticholinergic toxicity from atropine, scopolamine, and ditran. They may differ somewhat in the setting of other anticholinergic agents [19].

The characteristic general appearance of the anticholinergic syndrome is a restless, delirious patient who is picking at the bed sheets, clothing, and imaginary objects in the air. Speech is characteristically rapid, mumbling, and incomprehensible [20]. Hallucinations are usually visual but sometimes may be auditory. Dilated pupils and tachycardia are often present, but neither is essential to the diagnosis. Public disrobing is a common feature (particularly in plant-based toxicity), possibly due to the delirious uninhibited patient's sensation of flushing and hot skin [20].

Routes of Exposure

The anticholinergic syndrome may result from oral, pulmonary (smoking), ocular, dermal, buccal, rectal, or vaginal routes of exposure to anticholinergic agents. Oral exposures are most common in reported cases and include intentional ingestion of pills, seeds, or teas. Pulmonary or inhalational exposures usually are associated with substance abuse, although nebulized atropine treatment of asthma is an exception [21, 22]. Ocular and dermal exposures more commonly are unintentional exposures and are difficult to recognize. Witches' ointments were applied intentionally to the whole body, including the axillae, rectum, and vagina [9]. Horse traders rolled *Datura* leaves together and inserted them into the rectums of old nags to make them appear to be as fiery as thoroughbreds [9]. Exposure to ophthalmologic drops has resulted in the anticholinergic syndrome as an adverse effect of therapeutic use and has been an agent of drug-facilitated assault or robbery. Dermal exposures to topical diphenhydramine and scopolamine patches are well-known causes of systemic anticholinergic effects [23–26].

Intention or Cause of Exposures

Adverse Drug Reactions

Many authors have stated empirically that anticholinergic syndrome occurs frequently as an

adverse drug reaction, but few data have been published to support this. Anticholinergic adverse drug reactions occur most frequently as a result of increased sensitivity to a therapeutic dose or as a result of combinations of anticholinergic agents. Very young and very old individuals and patients with underlying organic brain syndromes are said to be more susceptible to CAS [4, 27, 28]. For unknown reasons, some patients have developed the anticholinergic syndrome from exposures to anticholinergic skin patches that most patients tolerate without problems. [29]

Unintentional Overdose

Toddlers and mentally infirm people are common victims of unintentional or accidental overdose. Use of combinations of prescribed or over-the-counter anticholinergic agents is a common cause of unintentional overdose.

Intentional or Suicidal Overdose

Suicidal ingestions of over-the-counter sleeping pills usually involve anticholinergic antihistaminic agents. Although these exposures are common and usually mild to moderate in severity, severe outcomes or death occasionally results [30, 31].

Recreational Abuse

Self-administration of anticholinergic agents to induce the desired euphoria, stupor, and hallucinations through induction of anticholinergism is well described [32, 33]. Abuse of anticholinergic drugs or natural substances is a particular problem of adolescents who are too young to buy alcoholic beverages legally [34–36]. In the fourteenth and fifteenth centuries, henbane often was added to beer for its hallucinogenic and mind-altering properties [9]. Anticholinergic agents prescribed to prevent or treat extrapyramidal or dystonic reaction due to neuroleptics have been abused by schizophrenics and individuals without psychiatric illnesses. In one study of schizophrenic patients, careful scrutiny revealed that 6.5% of 214 consecutively admitted schizophrenic patients abused trihexyphenidyl [36]. Emergency department physicians in the 1980s often gave a placebo saline injection to patients with suspected

dystonic reactions in hopes of discovering individuals with feigned dystonia who were seeking intravenous anticholinergic drugs [37–39]. The delayed absorption associated with these agents plus the biologic variability in natural substances makes it particularly difficult for users to titrate the dose of these agents to reach the desired end point of hallucinations while avoiding more severe toxicity.

Malicious Use

The addition of anticholinergic agents such as scopolamine to other substances of abuse may lead to unusual or serious toxicity. Substitution of scopolamine for cocaine [40] and addition of scopolamine to heroin [41] have been reported. Surreptitious addition of scopolamine to beverages is a well-known method of drug-facilitated sexual assault or crime [42–44]. The German term *Altsitzerkraut*, meaning “old sitter herb,” refers to the use of henbane to induce a lethal form of anticholinergic toxicity to murder an inactive old person [9]. Because there is no history of exposure in these cases and the usual simple toxicologic screens are negative, misdiagnosis is common.

Toxic Causes or Sources

Many types of prescription and over-the-counter medications and natural substances have anticholinergic properties (see Table 1). The anticholinergic syndrome may result from intentional or unintentional exposure to toxic amounts of these individual agents or in combinations. Many members of the plant family Solanaceae contain tropane or belladonna alkaloids. Plants that can cause the anticholinergic syndrome contain variable amounts of the following toxic alkaloids: solanine, atropine, and scopolamine. Anticholinergic plant toxicity is discussed in detail in the chapter devoted to that topic. Scopolamine is the primary tropane in Jimson weed. Toxin concentrations of specific types of plants and mushrooms are well known to vary with location, climate, and season. Natural brews, such as teas or wines made from these plants, are notorious for their intoxicating abilities [45–48]. Mushrooms containing muscimol/ibotenic acid are often described as capable of causing hallucinations and a syndrome

with some features that resemble the anticholinergic syndrome. However, muscimol and ibotenic acid are actually pharmacologic modulators of the gamma amino butyric acid – glutamic acid neurotransmitter system. Intentional (recreational) and unintentional (toddler ingestions) exposures to these types of mushrooms only rarely produce severe anticholinergic-like syndrome [49].

Range of Toxicity

Toxicity varies greatly among the various substances with anticholinergic properties. Toxicity is greatest for the TCAs primarily because of their α -adrenergic receptor-blocking and sodium channel-blocking effects rather than their anticholinergic properties. In a pediatric series of auto-injector atropine exposures, lower injected doses resulted mainly in mild peripheral effects, whereas higher doses resulted in hyperthermia and central effects [50]. In adults, atropine doses of 0.032 mg/kg caused peripheral effects and doses of 0.13–0.17 mg/kg caused central effects [19]. These studies suggest that peripheral effects occur at lower doses than do central effects. As little as 4–5 eye drops (probably less in children) containing 4% atropine or 0.25% scopolamine has been reported to cause the anticholinergic syndrome [51, 52].

Organ System Effects

Seizures

Anticholinergic poisoning is a common cause of drug-induced seizures, the risk of which may be agent-dependent. Seizures were not observed in a series of 20 cases of severe atropinization secondary to mostly unintentional auto-injector discharge during the Persian Gulf War [50]. In TCA overdose, the prevalence of seizures has been reported to be 3–30% [53–55]. However, the pathophysiology of TCA-induced seizures is poorly understood and may not be entirely due to their anticholinergic effects. In nine children hospitalized after ingesting *Amanita pantherina* or *Amanita muscaria* mushrooms, seizures or myoclonic

Fig. 3 Muscarinic signaling pathways in supraventricular (sinoatrial, atrial, and atrioventricular) myocytes. Acetylcholine (ACh) acts through M_2 receptors to regulate ACh-activated K^p channels via a membrane-delimited mechanism involving direct activation by the $\beta\gamma$ subunits of the inhibitory G protein G_i . ACh also acts through M_2 receptors to inhibit adenylyl cyclase (AC) activity via the α subunit (α_i) of G_i , resulting in a decrease in cAMP production. This may occur in the absence or presence of agonists that stimulate cAMP production. Norepinephrine (NEPi) acts through b_1 -adrenergic receptors to stimulate cAMP

synthesis by directly activating all isoforms of adenylyl cyclase (AC) via the α subunit (α_s) of the stimulatory G protein G_s . Changes in cAMP affect targets of protein kinase A (PKA)-dependent phosphorylation such as troponin I (TnI), phospholamban (PLN), and the L-type Ca^{2+} channel. Changes in cAMP also directly regulate pacemaker channels, which are permeable to both Na^+ and K^+ (From Handbook of Experimental Pharmacology Vol 208. Fryer AD et al. eds, 2012, Springer, Munich, with permission)

twitching occurred in 44% [49]. Understanding the true incidence of seizures may be clouded by abnormal muscle activity (e.g., jerks, twitches, rigidity) secondary to anticholinergic toxicity that may be confused with seizures by laypersons and less experienced health care providers. Because seizures have been considered by some to be a relative contraindication to physostigmine use, the reported observation of seizures by less experienced or trained personnel must be evaluated carefully.

Cardiovascular Effects

Mild to moderately severe anticholinergic syndrome is associated with sinus tachycardia and hypertension. The tachycardia may result primarily from blocking of the M_2 -receptors on the sinoatrial node.(Fig. 3). Hypertension results from

antagonism of the ACh-induced peripheral vasodilation (Fig. 4). However, anticholinergic agents that possess sodium channel or α -adrenergic antagonistic properties may result in hypotension due to direct vasodilation. Cardiotoxicity may further complicate hemodynamic instability due to development of advanced heart block or ventricular dysrhythmia. Together, these effects may lead to cardiovascular collapse and refractory shock. Of note, moderate anticholinergic exposure in a susceptible host may also lead to severe toxicity [56].

Gastrointestinal Effects

Anticholinergic agents may decrease intestinal peristalsis and delay gastric emptying [57]. For antispasmodic drugs, this is a desired effect and leads to decreased intestinal spasms. When

Fig. 4 Muscarinic signaling pathways in the vasculature. In endothelial cells, acetylcholine (*ACh*) acting through M_3 or M_5 receptors stimulates phospholipase C (*PLC*) activity through the G protein G_q . Subsequent production of inositoltriphosphate (IP_3) acts on the IP_3 receptor (IP_3R) in the endoplasmic reticulum to release Ca^{2+} . The resulting rise in cytosolic Ca^{2+} activates endothelial nitric oxide synthase (*eNOS*) via a calmodulin (*CM*)-dependent mechanism. Activation of *eNOS* leads to the production of nitric

oxide (*NO*), which can diffuse into adjacent vascular smooth muscle cells, where it stimulates soluble guanylyl cyclase (*sGC*) to produce cGMP. Protein kinase G (*PKG*) activated by cGMP promotes relaxation. In vascular smooth muscle cells, *ACh* acting through M_1 or M_3 receptors stimulates *PLC*-dependent production of IP_3 and the subsequent release of Ca^{2+} from the ER. This results in Ca^{2+} and *CM*-dependent kinase (*CaMKII*) activation of myosin light chain kinase (*MLCK*), which promotes contraction

undesired or excessive, these effects may lead to constipation or drug-induced ileus. This effect also may lead to delayed peak absorption and prolonged toxicity of anticholinergic agents as well as other co-ingestants.

Skeletal Muscle Effects

Severe forms of the anticholinergic syndrome may be associated with rhabdomyolysis resulting in release of myoglobin into the blood and nephrotoxicity [58–62]. Rhabdomyolysis in this setting may be a result of hyperthermia, excess motor activity or muscle tone, or dependent-type pressure injury secondary to deep coma.

Temperature Effects

Anticholinergic agents inhibit sweating, which reduces one's ability to dissipate excess body heat. Excess motor activity or muscle tone increases body heat. Hyperthermia can result from increased heat generation and impaired cooling secondary to sweating inhibition. This is especially true in environments with high ambient temperatures.

Urinary Tract Effects
